Leading Causes of Death

Expanded Edition

Including 1979-1998 Mortality Trends

Vital Statistics Volume 2 – 1998

Publications of the State Center for Health Statistics

Many of these publications are available online at http://www.schs.state.nc.us/SCHS/

North Carolina Health Statistics Pocket Guide (Biennial):

Data for the U.S., N.C., and N.C. counties are presented in tabular and narrative forms with more than 8,000 calculations depicting patterns of various needs indicators, as well as births, deaths, abortions, diseases, health care resources, and other data from state and national reporting systems and surveys. This composite of information, contained in a compact foldout, will serve the needs of many health data users.

North Carolina Vital Statistics, Volume 1: Population, Births, Deaths, Marriages, Divorces (Annual):

For the state and each Perinatal Care Region (PCR), county, and major incorporated city, one-page tables summarize annual and 5-year data by race and selected variables. Maps, graphs, and narrative describe geographical patterns and statewide trends.

North Carolina Vital Statistics, Volume 2: Leading Causes of Death (Annual):

For the state and counties, cause-specific annual and 5-year data are given in the form of numbers of deaths, unadjusted death rates, and age-adjusted death rates. For each cause, maps depict 5-year adjusted and unadjusted county rates. Infant mortality data are also tabulated and mapped.

Basic Automated Birth Yearbook, North Carolina Residents (Annual):

Known as the BABY BOOK, this statewide report is comprised of multiple cross-tabulations of various maternal and infant variables such as age, race, birth order, birth weight, and number of prenatal visits as well as medical conditions of the mother, the labor/delivery, and the newborn. Data for North Carolina counties are available on microfiche.

Detailed Mortality Statistics, North Carolina Residents (Annual):

This statewide report provides annual counts of deaths specific for detailed underlying cause of death (4 digits) and agerace-sex group. Data for counties are available on microfiche.

North Carolina Reported Pregnancies (Annual):

For the state, PCRs, and counties, annual estimates of pregnancy rates, live birth rates, abortion rates, and abortion fractions by age and race are followed by one-page tables displaying counts of pregnancies (abortions, live births, and fetal deaths) by race and age for total and unmarried women. Maps, graphs, and narrative describe geographical patterns and statewide trends.

Cancer Incidence in North Carolina, County-Specific Numbers (Annual):

Observed and expected numbers of newly diagnosed cancer cases for 26 cancer sites and total cancer are provided by county and gender. State and county tabulations of cases by race-sex and age are also provided.

North Carolina Cancer Facts and Figures (Biennial):

This collaborative report with the American Cancer Society is prepared specifically for use by the public. It contains tabular, graphic, and narrative materials regarding cancer in North Carolina. Information about cancer control activities and agencies in the state is also given.

Local Health Department Facility and Staffing Report (Biennial):

Facility-level data are compiled from health department surveys. Capacity of facilities, staffing levels, and expenditure data are provided.

SCHS Studies (Intermittent):

Studies on health topics of current interest are presented in newsletter form.

Statistical Brief (Intermittent):

These shorter reports on health topics are designed to provide quick information for health decision makers.

Statistical Primer (Intermittent):

Short tutorials on statistical methods are presented in newsletter form.

An Inventory of North Carolina Health Data (Intermittent):

This publication describes by subject-matter health data sets existing in public and nonpublic agencies. Included in the description are the data set's location, the data collection interval, the smallest unit of analysis, whether computerized, and the name of a contact person.

Introduction

This publication shows death rates for the twenty years of mortality data (1979-1998) coded under the International Classification of Diseases, 9th Revision (ICD-9). Beginning in 1999 causes of death have been coded using the 10th Revision of the ICD. The State Center for Health Statistics produces a major publication annually, describing in tabular and map form North Carolina's mortality experience over the most recent five-year period. Periodically, an expanded volume is produced that includes a narrative analysis for each cause of death. The expanded format is resumed in this 1998 edition, which includes statistical tables, maps, and graphs, as well as discussions of cause-specific trends, geographic patterns, risk factors, and pertinent research. An overview of mortality in North Carolina is also presented.

The tables in this report provide selected mortality statistics for counties and the state. More than a dozen of the leading causes of mortality in North Carolina are tabulated; in addition, four major cancer sites and total infant mortality are included.

Four five-year death rates are presented here for the state and each county: 1979-83, 1984-88, 1989-93, and 1994-98. In keeping with the new convention of the National Center for Health Statistics, all age-adjusted death rates use the projected year 2000 population for the United States as the standard population. As a result, the adjusted rates in this volume will not be comparable to those published in previous editions of *Leading Causes of Death*. A Technical Notes section defines death rates and the methods for age adjustment of death rates. The reader is urged to consult this section prior to using the data in this volume. Also, please refer to the Appendix for a more detailed discussion of age-adjusted death rates.

A more exhaustive breakdown of cause-specific mortality by age, race, and sex is described in the companion volume, *North Carolina Detailed Mortality Statistics*. This and other publications (listed and described on the inside front cover of this publication) are available through the State Center for Health Statistics. If you would like copies of these publications you may contact the Center's Information Services Unit. Many of them are also available online at http://www.schs.state.nc.us/SCHS/.

Organization of this Publication

The first sections of this edition of *Leading Causes of Death* present an overview of mortality in North Carolina and discussions of premature mortality and racial/ethnic differences in mortality. The next sections consist of tabular data, maps, and narrative material which describe North Carolina's recent experience with respect to total mortality and cause-specific mortality. For each cause, risk factors, geographic patterns, differences by race and sex, and trends over time are considered.

A Technical Notes section provides information concerning the calculation, interpretation, and appropriate use of adjusted and unadjusted rates. Readers are cautioned about using rates based on a small number of deaths. Any death rate with a small number of deaths in the numerator will have substantial random variation over time. A good rule of thumb is that any rate based on fewer than 20 events in the numerator may be subject to serious random error. Many of the death rates in this report have numerators smaller than 20, and so extreme caution should be taken when making comparisons or assessing trends.

Appendix A describes the selected cause-of-death categories in terms of codes from the ninth revision of the International Classification of Diseases. Altogether, the major causes selected for examination in this report accounted for 82 percent of all North Carolina deaths during 1998. Data for some of the specific cancer sites listed in Appendix A are not presented at the county-level in this report, due primarily to the relatively small numbers of deaths.

Description of Tables

Except for infant deaths, a table for each cause-of-death category includes the following items of information for the state and each county of residence:

- 1. The number of resident deaths occurring during 1998;
- 2. The 1998 death rate:
- 3. The number of resident deaths occurring during 1994-98;
- 4. The 1994-98 average annual death rate;
- The 1979-83, 1984-88, 1989-93, and 1994-98 average annual age-adjusted death rates computed by the direct method, using the projected United States 2000 population as the standard for adjustment.

The formulas for calculating single- and five-year rates are described in the Technical Notes section. In this report, total mortality rates (all causes combined) are expressed as deaths per 1,000 population. Cause-specific rates are expressed as deaths per 100,000 population. The infant death rates of Table 21 are computed as the number of infant deaths per 1,000 live births.

Description of Maps

This publication contains 19 sets of maps which depict data for the state's 100 counties. (See inside of back cover for a map with county names.) For total mortality and each cause of death, the 1994-98 unadjusted death rates and the 1994-98 age-adjusted death rates are mapped. These maps show five levels of death rates. The interval values (levels) indicated by the map legends are not necessarily continuous, but reflect the actual range of values for each interval. These maps must be viewed with caution for causes where the number of deaths per county is small, since in these cases rates can be unstable. A clustering routine from the Statistical Analysis System (SAS) was used to group counties that are "most like each other" with respect to their unadjusted and adjusted rates. This procedure may result in very large or very small groups, depending upon how county rates differ from one another.

Overview of Mortality in North Carolina

Total mortality in North Carolina has exhibited an overall downward trend in this century, but an upward trend since 1982, rising from a low of 8.1 deaths per 1,000 population in 1982 to a high of 9.0 in 1998. Probably the major factor contributing to this increase is aging of the state's population. Other factors that affect mortality include changes in lifestyle (e.g., reduction in smoking), environment, and the medical care system. This overview summarizes four general determinants of mortality as well as some of the risk factors that are associated with a number of different causes. Then premature mortality in North Carolina is examined via the concept of "years of life lost," which emphasizes the impact of mortality in the younger age groups.

Determinants of Mortality

A broad view of mortality determinants shows that problems "arise from causes embedded in the social fabric of the nation as a whole", and that medical care is only one aspect of health maintenance. Accordingly, environment, lifestyle, biology and genetics, and medical care must all be considered as determinants of health.

Over the past decades, *environmental factors*, both natural and man-made, have been increasingly recognized as having a significant impact on health. For example, naturally occurring variations such as water mineral content and elevation have been cited as influencing the incidence of cardio-vascular disease². Another problem may be the natural occurrence of radon gas in some homes. However, most serious environmental problems are consequences of man-made pollution of air^{3,4}, water, and food sources. Recent examples include atmospheric pollution from lead and ozone, ground water contamination from toxic wastes, and occupational exposures to hazardous substances. Children are especially at risk from pollutants such as ozone^{5,6} and lead.^{7,8}

While pollution is a by-product of a high-technology, growth-oriented society, some favorable consequences of economic growth include jobs, income, health insurance, and improved access to medical care. Unemployment and poverty are generally associated with less adequate mental and physical health. The poor, having fewer economic and social resources, experience higher levels of stress and are more vulnerable to infectious agents, economic problems, and hazards in the home and workplace. Rural populations are less likely to have medical insurance and good access to medical care. In short, economic conditions and environmental factors may interact in complex ways to affect health status.

Lifestyle refers to behaviors that affect health and over which individuals have varying degrees of control. There are substantial data showing that certain health habits (e.g., never having smoked, moderate or no alcohol consumption, regular exercise, sleeping 7-8 hours per night, and maintaining appropriate weight) are associated with improved health and reduced mortality. Individuals' lifestyle decisions are associated with their socioeconomic status, race, and sex. Men are more likely than women to smoke and drink excessively; younger women are more likely to smoke than older women; blacks are more likely to be sedentary than whites; and black women are substantially overweight almost twice as often as white women. Persons with fewer than 12 years of education are more likely to smoke, not exercise, and be substantially overweight. Individuals' lifestyle decisions are significantly influenced by their demographic characteristics and socioeconomic status. Blaming the victim by keeping the problem only at the individual level may obscure some of the origins of disease in the socioeconomic environment. Policies to educate individuals about their health behaviors are less complex and easier to sell politically than those aimed at modifying the underlying social and economic determinants of lifestyle and health.

Health education of individuals is an important component in improving health. Certain population groups are more likely to have lifestyles associated with increased mortality, and education programs are effective complements to policies oriented toward the environmental factors that condition lifestyle. For example, nutrition education can have a substantial health payoff among the poor, but the payoff will be much higher if they have sufficient money to buy proper foods and facilities for preparation. Sex education for prevention of sexually transmitted diseases and unwanted pregnancies is another area where education may be very effective in altering specific high-risk behaviors. Income, education, and urban/rural residence are important indicators and determinants of lifestyle, and effective education programs must consider these factors. Targeting specific high-risk groups is likely to be more successful than generalized education or media campaigns.

Biological factors are powerful determinants of mortality. The age, race, and sex of an individual are biologically determined, and mortality rates vary consistently along these dimensions. For example, health is strongly tied to aging and the life cycle. Some diseases that vary by race are thought to be genetically linked. Biological factors in part account for the higher rate of some diseases in men as compared to women, with women living longer on the average. However, there are health consequences of age, race, and sex that are not biological in origin. Social stratification is partly based on these variables, with the elderly, minorities, and females generally being accorded lower socioeconomic status in the United States. Some of the elevated male mortality may result from the aggressive, achievement-oriented lifestyle that accompanies higher status positions, while higher mortality among persons of racial and ethnic minorities is due in part to a lower position in the economic hierarchy.

A number of diseases are directly or indirectly genetic in origin. In North Carolina, many people are afflicted with serious genetic disorders, resulting in physical defects, mental retardation, and other health problems, and a significant percentage of birth defects are genetic in origin.¹⁴ It has been estimated that 12 percent of pediatric hospitalizations are related to birth defects and genetic diseases,¹⁵ and about 50 percent of all childhood blindness is linked to genetic factors.¹⁶ In North Carolina, congenital malformations are a leading cause of mortality among infants under one year, and second only to injuries among children ages one through four. Overall, the 1998 congenital anomalies death rate was 5.1 deaths per 100,000 population. This is only a slight decline from a rate of 5.3 in 1988. In addition, some persons have a genetic susceptibility to certain diseases. Many types of cancer, for example, have genetic origins.¹⁷

The *medical care* system is another important determinant of mortality levels. It responds to health problems by attempting to restore the individual to a full and productive life. Disease prevention is also within the purview of the medical care system, as exemplified by vaccination to prevent infectious diseases and by patient education concerning health consequences of certain behaviors. Medical care personnel may also be involved in addressing certain environmental causes of disease, though this type of activity has traditionally been carried out by the public health sector.

McKeown and Brown¹⁸ present evidence suggesting that medical practice in the first half of the 19th century had little to do with the large decline in mortality that took place in Western societies. They suggest that transportation improvements, changes in the economic system that assured a more continuous and nutritious food supply, and improved sanitation practices in the cities were responsible. After the practice of antisepsis became widespread late in the 19th century, medical care became a much more positive factor in reducing mortality. During the first half of this century, the health and average life span of Americans improved considerably, due substantially to efforts in the medical sector to reduce infections and acute nutritional diseases. Major gains were also observed in infant and maternal mortality, probably due to improvements in nutrition, sanitation, and the development of vaccines.¹⁹

Medical care may sometimes have negative health consequences. It has been estimated that infections acquired inside the hospital strike five percent of Americans hospitalized each year, adding to hospital costs and increasing lengths of stay. ^{20,21,22} Inappropriate or unnecessary treatment may increase mortality as well as health care costs. Risks are always present, even in proper medical treatment, but in most cases they are far outweighed by the potential benefits.

In summary, a complete program to improve health status and reduce mortality must include environmental, lifestyle, biological, and medical care strategies. Too much emphasis in one area may involve substantial opportunity costs due to neglect of other areas. For example, expenditures for basic research, for environmental protection, to improve substandard housing, or for public education regarding specific risk behaviors could have higher long-term health payoffs than would the same amount expended just for medical care. The status of heart disease and cancer as major killers is closely linked to lifestyle and environmental factors. Sedentary occupations and consumption of foods high in animal fats contribute to both heart disease and cancer. Increased economic production and consumption have led to more exposure of the population to carcinogens in air, water, and food. Effective cancer control will require fundamental changes in the environment as well as modification of behaviors and lifestyle. In short, strategies to reduce cancer, heart disease, and other leading causes of mortality must deal with factors in the fabric of contemporary society.

Risk Factors

Risk factors particular to each cause of death are discussed in separate sections of this volume. Information about several factors that are common to a number of different causes of death is summarized here.

Two of the most pervasive factors contributing to mortality from various diseases are *high blood pressure* and *cigarette smoking*. Elevated blood pressure is associated with death from all cardio-vascular diseases, diabetes mellitus, cirrhosis of the liver,^{23,24} and renal failure.²⁵ While most causes of hypertension are amenable to treatment, many people either are unaware of having the condition or do not modify behaviors to control it (e.g., maintain proper weight, diet, and medication regimen).

Use of *tobacco products* contributes to death from a large number of causes. ^{23,24,26-29,30} According to data compiled by the U.S. Surgeon General, ²⁹ cigarette smoking is a major cause of lung cancer as well as cancers of the larynx, oral cavity, and esophagus; it is a contributory factor in the development of cancers of the bladder, pancreas, and kidney; and approximately 30 percent of all cancer deaths are attributable to cigarette smoking. There is evidence that it is a contributor in the development of chronic bronchitis and emphysema, pulmonary heart disease, myocardial infarction, aortic aneurysm, and a wide variety of other vascular diseases. In addition, smoking seems to interact with other risk factors, such as asbestos, ionizing radiation, oral contraceptives, and certain dietary factors, to produce a variety of cancers and vascular diseases. Use of smokeless tobacco (snuff, chewing tobacco, and similar products) is associated with tongue cancer and oral cancers in general. ^{31,32} There is also substantial evidence that environmental tobacco smoke (passive smoking) is associated with increased mortality. ³³

Diet has an important impact on certain causes of mortality. Overeating may lead to obesity, which is associated with high blood pressure, diabetes, cardiovascular disease, and overall mortality. ^{34,35,36} In turn, diabetes is a risk factor for stroke and other cardiovascular diseases. In addition, the content of the modern diet has important consequences for mortality. The contemporary diet "…is

higher in intake of energy, of protein (especially animal protein), and of fat (especially animal fat), but lower in intake of fiber-containing cereal foods; this diet is associated with high rates of morbidity and mortality from degenerative diseases".³⁷ Decreased intake of animal fat and protein, cholesterol, salt, sugar, and alcohol are often recommended. In addition, inadequate nutrition, irrespective of obesity, is associated with a higher risk of certain diseases.^{38,39}

Excessive alcohol consumption is a very large health problem in America⁴⁰ and is associated with a high risk of premature death from a variety of diseases.⁴¹⁻⁴³ "While the lifestyle typical of many heavy drinkers contributes to this risk, the effects of alcohol *per se* account for a substantial part of the excess mortality".⁴¹ In two Chicago studies, heavy drinkers had higher mortality from all causes, cardiovascular diseases, coronary heart disease, and sudden death than could be entirely explained by other risk factors such as blood pressure, smoking, and weight.⁴² Heavy alcohol use by pregnant women leads to birth anomalies, including fetal alcohol syndrome and subsequent mental retardation.^{40,44} Alcohol consumption increases the risk of mortality from homicide, suicide, and unintentional injury.⁴³

Socioeconomic status has a very strong impact on mortality.^{13,27,45-47} "Social class gradients of mortality and life expectancy have been observed for centuries, and a vast body of evidence has shown consistently that those in the lower classes have higher mortality, morbidity, and disability rates".¹³ Differences between white and minority mortality rates can be attributed largely to the lower average socioeconomic status of minorities. Minorities are more likely to live in substandard housing and other hazardous conditions, resulting in an array of disease consequences. Low education contributes to poor health practices, and low income affects many aspects of health, including nutrition. Higher stress levels and ineffective responses to stress also contribute to higher mortality among the poor.¹³

Persons of lower socioeconomic status generally receive less adequate medical care, though this probably does not account for a major portion of the socioeconomic differences in morbidity and mortality.¹³ In fact, the association between excess mortality and low socioeconomic status persists independent of individual behaviors or attributes such as smoking, alcohol consumption, body mass index, physical activity, martial status, race, and sex.⁴⁸ Properties of the socioeconomic environment are important contributors to the excess mortality.⁴⁹

Social isolation is associated with an increased risk of mortality. Persons with strong social support and social networks have lower mortality risk, independent of other risk factors. Married persons have a significantly lower risk of mortality than those who are divorced, single, separated, or widowed, though this relationship may be due to factors besides protective effects of marriage itself. 54,55

Sex is another important variable associated with mortality. Females have lower mortality rates and greater life expectancies than males in all developed countries.⁵⁶ The differential in death rates is present at conception and continues for every age group. At birth, the ratio of males to females is 104:100, but by age 70 females outnumber males by approximately 3:2.

A substantial amount of excess male mortality is related to sex differences in behavior, such as cigarette smoking, drinking alcohol, aggressive competitiveness, and occupational exposure to environmental and physical hazards. For 15-44 year-olds, more than 90 percent of the excess male mortality may be attributable to violence and smoking. Biological factors also contribute to higher male mortality. Thus, even among nonsmokers, men have higher mortality than women for certain types of cancer, and this implies that there must be other factors, in addition to smoking, that contribute to higher cancer among men".

To the extent that the sex difference in mortality is not due to biological factors, substantial reductions in male excess mortality may be possible through lifestyle and behavioral changes. With the transition earlier in this century from infectious to degenerative diseases as the major causes of death, lifestyle became more important in affecting mortality experience, and the difference between male and female mortality rates increased steadily. More recently, female mortality relative to male mortality has actually worsened for several age groups and for several leading causes. This may be associated with increased smoking and the adoption of other "male" behaviors by women as job participation and mobility increase and traditional roles are modified. Thus, social and lifestyle changes may also help to reduce female mortality.

A number of risk factors have been reviewed that bear on many causes of death, and efforts to reduce mortality must involve consideration of these important precursors.

Premature Mortality in North Carolina

Since 1914, when deaths were first centrally recorded in North Carolina, the leading causes of mortality have usually been ranked according to number of deaths. North Carolina deaths in 1998 have been ranked in Table A based on this traditional method. As shown, heart disease and cancer are the leading causes of death, followed by stroke (cerebrovascular disease) and unintentional injuries.

Rankings based only on number of deaths (or rate per 100,000 population), however, do not necessarily indicate where medical and public health intervention strategies can be most effectively employed. Since death is postponable but not preventable, age at death is a key factor to consider. Prevention of a death that would otherwise occur early in life could be assigned higher priority than prevention of a death later in life. A convenient method of ranking causes of death that incorporates age at death is by "years of life lost". If the average life expectancy at birth for white males, for example, is 72 years, a death at age 65 would mean seven years of life lost (on the average), while a death at age 40 would mean 32 years of life lost. A white male infant death results in 72 years of life lost, whereas deaths at ages 72 and over do not contribute to years of life lost for white males. Based on the 1989-91 life tables for North Carolina, the life expectancies used here to calculate years of life lost were 72 for white males, 79 for white females, 65 for minority males, and 75 for minority females. For each death in a given cause group, age at death was subtracted from the appropriate life expectancy and all of these life-years lost were then summed across the four race-sex groups. Deaths at ages greater than the specified life expectancies were not counted.

Table B displays the leading causes of death in 1998 ranked according to years of life lost. Heart disease and cancer are still very important causes of death from this perspective, but other causes become much more prominent than before. Unintentional injuries (motor vehicle injuries and other unintentional injuries) rank much higher in terms of years of life lost. Motor vehicle injury decedents are on average about 28 years younger than heart disease decedents. Likewise, cancer decedents are on average several years younger than heart disease decedents.

Racial and Ethnic Differences in Mortality

Graphs of trends in age-adjusted death rates for whites and minorities are included in each cause-of-death section. These graphs show single-year age-adjusted death rates for the years 1979 through 1998. These graphs will help identify causes of death where there are large racial disparities in mortality and portray changes in the patterns over time. The county-level mortality data in this publication are not broken out by race, in part for statistical reasons. Many counties have a very small minority population and the number of deaths, even for a five-year period, would be too small to produce reliable age-adjusted death rates for specific causes of death.

There are advantages of showing mortality data by race, to target resources and interventions toward populations most in need. However, hazards exist in interpreting the data. Race in and of itself does not generally cause poor health status. We do not have a complete understanding of why race is associated with health problems, but it is likely that factors such as socioeconomic status, stress, and racism are among the underlying causes of the higher mortality of minorities (on average) compared to whites. Few of our health data have these types of information recorded, while most do have information on race. Thus, race often serves as a surrogate measure for a variety of other factors. Still, there is wide interest in North Carolina in descriptive health statistics broken out by race.

The State Center for Health Statistics normally publishes data by race for only two groups: white and minority. We do recognize and appreciate the various population groups in North Carolina and the need for more details on race, such as for American Indians and Asians. Several factors have hampered efforts to obtain accurate data for specific minority populations. In addition to the issue of small numbers leading to unreliable rates, there are other technical reasons why we usually show data for only the two race groups. First, detailed census data on race is collected only once every ten years. The racial structure of North Carolina's population can change dramatically over the course of a decade. Therefore, as years pass after the latest census, it is more difficult to extrapolate accurate population figures. Second, the State Center relies on annual population estimates supplied by the North Carolina Office of State Planning. They produce official annual population estimates only for "white" and "other." For this reason, the appropriate denominators to produce rates for specific racial groups are not routinely available.

A similar problem exists when attempting to study mortality rates by Hispanicity. The Hispanic/Latino population is an ethnic group, rather than a racial group, and Hispanics may be counted in both white and minority racial groups in our death files. In addition, as with racial groups, there are significant challenges in collecting accurate population data for Hispanics. Over the course of the last decade North Carolina has experienced a dramatic increase in its Hispanic/Latino population. However, population data for Hispanics/Latinos are based on the 1990 census and it is likely that these are underestimates of the true population.

In an effort to address these concerns, the State Center plans to develop its own estimates of the population of specific racial and ethnic groups. A special study is planned which will examine racial and ethnic differences in mortality in greater detail.

In addition to the trend graphs of white and minority age-adjusted deaths rates shown in each cause-of-death section, two tables are included here that portray state-level differences in cause-specific mortality by race and race-sex for the period 1994-1998 (Tables C and D). These tables show numbers of deaths and age-adjusted death rates for whites and minorities and for white males, white females, minority males, and minority females. In North Carolina, approximately 90 percent of the minority population is African American, so the data for minorities in this publication will closely reflect the experience of African Americans.

^{*}Leading causes of death are generated from a list of 43 causes of death categories developed by the National Center for Health Statistics to promote comparability in analyses of mortality. For deaths under one year of age, a list of 27 causes of death was used. See Appendices for the ICD-9 codes for these lists of causes.

^{*}Racial group totals will not add up to overall total because deaths occurring among other races are not included here. Caution should be taken when comparing the number of deaths across racial groupings. Population size varies considerably from one racial group to another. The number of deaths for each group is to a large extent a reflection of that population size.

Table J: Sex-Specific Mortality Statistics Summary for 1998 North Carolina Male and Female Residents*

Cause of Death	Number of Deaths 1998	Death Rate 1998
Cancer		
Female Breast	1,163	29.9
Cervix Uteri	124	3.2
Ovary & Other Uterine Adnexa	333	8.6
Prostate	983	26.9

Note: The death rate for all causes is per 1,000 population while cause-specific death rates are per 100,000 population. The death rates in Table J cannot be compared to those in Table I because the denominators are sex-specific. Therefore, in ranking the causes of death—for example, in ranking the leading cancer sites—one must use the observed <u>numbers</u> of deaths.

^{*} See Appendices for Cause of Death codes.

Total Deaths – All Causes

Introduction

During 1998 a total of 67,798 North Carolinians died. This number represents an annual death rate of 9.0 resident deaths per 1,000 population. One confounding factor in making comparisons of mortality rates is that age structure of a population, which has an important impact on mortality, may vary among geographic areas and over time. It is important to adjust for age when comparing death rates among counties within North Carolina. Also, adjustment for age affects comparisons of North Carolina to the nation as a whole. North Carolina's unadjusted overall death rate for 1997 of 8.9 was 3 percent higher than the 1997 death rate for the United States of 8.6.¹ After adjustment for age, North Carolina's 1997 death rate was 7 percent higher than that for the United 'States. This suggests that North Carolina has a somewhat younger population than the nation as a whole. Since death rates are much lower in the younger age groups, a younger population will tend to reduce the unadjusted death rate.

Differentials and Trends

While the North Carolina trend for unadjusted rates indicates some increase in mortality, due to aging of the population, examination of age-adjusted rates shows a different pattern. From 1979-83 to 1994-98 the risk of death for North Carolinians declined by 8 percent, from 10.2 to 9.4 per 1,000 population (using the projected United States year 2000 population as the standard for adjustment).

General comparisons or mortality can mask variations by race and sex. Looking at North Carolina deaths in the 1994-98 period, the age-adjusted male rate (12.1) exceeded the female rate (7.6) by 59 percent. There is little difference in the 1994-98 unadjusted death rates by race: 9.0 for whites compared to 8.9 for minorities. The minority population has a younger age distribution than whites and this accounts for their similar unadjusted death rates. Comparing the age-adjusted death rates for 1994-98, the rates are 11.9 for minorities and 8.8 for whites. By race and sex, the age-adjusted death rates for 1994-98 were as follows: 11.2 for white males, 7.1 for white females, 15.9 for minority males, and 9.3 for minority females. In the following sections, important differences in the risk of mortality by race and sex groups are described for the major causes of death.

Risk Factors

See the section "Overview of Mortality in North Carolina" for a review of general mortality risk factors.

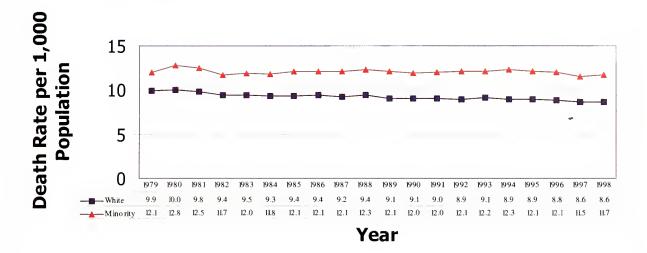

Geographic Patterns

The 1994-98 unadjusted total mortality rates for counties ranged from 14.1 in Polk County to 5.6 in Wake County, with a state rate of 9.0 per 1,000 population. Figure 1.C shows several scattered groups of high-rate counties, with the northeast having the largest cluster. This general pattern persists in eastern North Carolina after adjustment for age (Figure 1.D), which indicates that factors other than age distribution are causing the higher rates in these counties. Figure 1.D shows a large band of contiguous, high-rate counties extending from Virginia to South Carolina in the eastern third of North Carolina.

Heart Disease

Introduction

Heart disease is the leading cause of death in North Carolina and in the nation. In 1998, heart disease was responsible for 19,441 deaths in North Carolina; accounting for 29 percent of all deaths in the state. Heart disease has an overall mortality rate of 257.6 per 100,000 North Carolina residents.

Differentials and Trends

In 1998, the age-adjusted heart disease mortality rate was 59 percent higher for males*(339.5 per 100,000 population) than for females (213.6). In addition, the 1998 age-adjusted heart disease mortality rate was 26 percent higher for minorities than for whites (319.6 vs. 254.4 per 100,000 population). Between 1979 and 1998, the North Carolina age-adjusted heart disease mortality rate declined by 34 percent. Despite the overall reduction in heart disease deaths, important differences exist in the rates of decline by race and sex. From 1979 to 1998, the age-adjusted heart disease mortality rate decreased 37 percent among whites — from 402.0 to 254.4; but only 22 percent among minorities — from 409.6 to 319.6. During this same time period, the age-adjusted heart disease death rate declined 39 percent among males, from 554.4 to 339.5, but only 28 percent among females, from 297.6 to 213.6.

These age-adjusted heart disease mortality trends indicate a growing gap between minorities and whites, and a narrowing gap between males and females. In 1979, the heart disease mortality rate for minorities and whites was essentially the same, but by 1998 the rate was 26 percent higher for minorities than for whites. In contrast, the gap between males and females decreased during this same period. The heart disease mortality rate for males was 86 percent higher for males than for females in 1979, and 59 percent higher in 1998.

Risk Factors

Risk factors for heart disease include obesity, physical inactivity, poor nutrition, tobacco use, high blood pressure, elevated cholesterol, and diabetes.¹ Changes in lifestyle factors, such as smoking cessation and weight control, coupled with improved access to early detection and better medical treatment have led to the decline in heart disease deaths during the past 20 years. The primary modifiable risk factors for heart disease are tobacco use, physical inactivity, and inadequate nutrition.²

Cigarette smoking is so significant a risk factor that the Surgeon General has called it "the most important of the known modifiable risk factors for coronary heart disease in the United States". Smokers are twice as likely as nonsmokers to suffer a heart attack and have two to four times the risk of nonsmokers for sudden cardiac death. Further, smokers who have a heart attack are more likely than nonsmokers to die and die suddenly (within an hour). In 1997, 26 percent of North Carolina adults were current smokers. This was the eleventh highest prevalence in the nation, above the United States median of 24 percent.

Physically inactive people are almost twice as likely as those who engage in regular physical activity to develop heart disease.⁶ Regular moderate-to-vigorous physical activity plays a significant role in preventing heart disease, and helps to control other risk factors, such as obesity, high blood

pressure, and elevated cholesterol.⁴ Risk from physical inactivity is comparable to the highly recognized risks of smoking, high blood pressure, and elevated cholesterol. However, physical inactivity is more prevalent than any of these risk factors.⁶ Physical inactivity poses a serious health threat to North Carolinians. In 1996, only 14 percent of North Carolina adults engaged in regular and sustained physical activity. This was the eighth lowest prevalence in the nation, falling below the United States median of 21 percent.

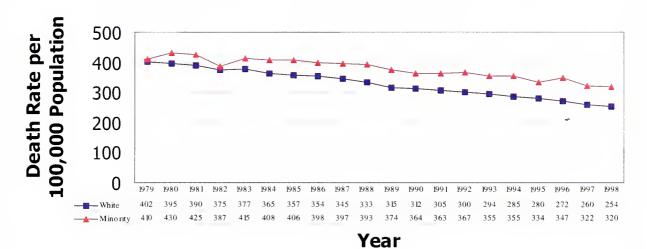

Poor diet is another leading contributor to heart disease. A diet high in fat contributes to elevated cholesterol, obesity, and diabetes.⁷ Despite having many healthy food options available, North Carolinians generally consume a high-fat, low-fiber diet, and the proportion of who are overweight is increasing.⁵ In 1996, only 17 percent of North Carolina's adults reported eating at least five fruits and vegetables daily. This was the fifth lowest prevalence in the nation, falling below the United States median of 24 percent. Further, 31 percent reported being overweight, the twentieth highest prevalence in the United States.

Geographic Patterns

While the heart disease death rate is decreasing overall in the state, relatively high unadjusted rates remain in several parts of North Carolina. After adjusting for age, several pockets of counties in the eastern part of the state and along the South Carolina border continue to have high rates, indicating that these counties are experiencing high heart disease mortality that cannot be explained by age. These counties tend to be rural and have poorer socioeconomic profiles. In contrast, urban counties, such as Buncombe, Mecklenburg, and Wake, exhibit relatively low rates of age-adjusted heart disease mortality.

Cerebrovascular Disease

Introduction

In 1998 cerebrovascular disease, or stroke, claimed the lives of 5,434 North Carolinians with a death rate of 72.0 per 100,000 population. It ranked as the third leading cause of death behind heart disease and cancer, accounting for 8 percent of all deaths in the state. From 1979 to 1998, the age-adjusted cerebrovascular disease death rate declined every year. During this time period, the rate dropped 37 percent from 119.8 to 75.5 per 100,000 population.

Differentials and Trends

Despite this impressive drop in overall mortality, minorities continue to have exceedingly high rates of cerebrovascular disease deaths. In 1998, the age-adjusted cerebrovascular disease death rate for the minority population was 46 percent higher than for the white population (101.6 vs. 69.7 per 100,000 population). From 1979-1998, the rates diverged, decreasing less for the minority population than for the white population (25 and 40 percent, respectively).

In 1998, the age-adjusted cerebrovascular disease death rate for males of all races was 10 percent higher than for females (79.3 vs. 72.0 per 100,000 population). From 1979-1998, the gap between males and females has narrowed as the rate for males declined more than for females (40 and 35 percent, respectively).

According to 1997 data, North Carolina's cerebrovascular disease death rate is the fourth highest in the nation.¹ This high ranking establishes North Carolina in the "stroke belt," which is an 8- to 10-state region in the southeastern United States. Death rates in the stroke belt are 1.3 to 2.0 times the national average. Individuals living in the stroke belt have a 43 percent greater risk than those living elsewhere in the U.S. of death from a stroke.²

Risk Factors

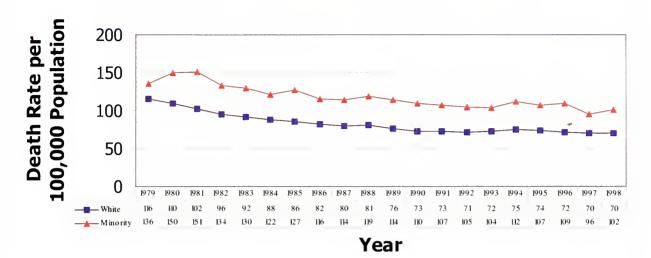

Many of the risk factors associated with cerebrovascular disease are the same as those for heart disease: obesity, physical inactivity, cigarette smoking, high blood pressure, elevated cholesterol, and diabetes. Additional risk factors include prior stroke, carotid artery disease, heart disease, transient ischemic attacks, and high red blood cell count.³ Minorities are also at greater risk of dying from cerebrovascular disease. The large racial differences we see in cerebrovascular disease death rates is, to some extent, due to a generally higher prevalence of risk factors (except for smoking) and lower prevalence of preventive practices.⁴

Geographic Patterns

Geographically, there is a scattering of counties with relatively high unadjusted rates, with several pockets of high-rate counties in the eastern and western parts of the state. After adjusting for age, the majority of high-rate counties are clustered in the east. The eastern part of the state is included in the "buckle" of the stroke belt, along with the coastal regions of South Carolina and Georgia. These areas have drastically elevated rates of stroke, even compared with the rest of the stroke belt.²

Cancer

Introduction

Cancer is a group of different diseases characterized by uncontrolled growth and spread of abnormal cells. If the spread is not controlled, it can result in death. Cancer is caused by both external (chemicals, radiation, and viruses) and internal (hormones, immune conditions, and inherited mutations) factors. Causal factors may act together or in sequence to initiate or promote carcinogenesis, and often ten or more years pass between exposures or mutations and detectable cancer.

Cancer is one of the most common causes of death in North Carolina — second only to heart disease. However, while the age-adjusted death rate for heart disease has declined steadily over the past twenty years, death rates for cancer have remained relatively unchanged over time. In 1998, a total of 15,327 North Carolinians died from cancer; representing about one in five deaths in the state.

Differentials and Trends

The state's 1998 cancer death rate was 203.1 deaths per 100,000 population. The state's age-adjusted cancer death rate for 1994-98 was two percent less compared to the previous five-year period (1989-93), but still higher than the rate for 1984-88.

Comparisons of changes in the age-adjusted rates for race-sex groups also reveal small decreases over the past few years. Death from cancer is rare under the age of 35 and the number of deaths peaks in the 70-74 age group, in which 16 percent of 1997 cancer deaths occurred. Comparisons of the age-adjusted rates for race-sex groups shows higher mortality rates among males, especially minority males who have twice the overall cancer mortality rate of minority females (382.6 versus 192.1).

Risk Factors

Cancer is a number of different diseases and the risk factors vary by type. Cancer risk factors are discussed in detail in the narratives for the four major types of cancer: colon and rectum; trachea, bronchus, and lung; female breast; and prostate.

Geographic Patterns

Unadjusted and age-adjusted county cancer death rates for 1994-98 are mapped in figures 4.C and 4.D respectively. Crude mortality rates are higher in the northeastern and southwestern portions of the state. These regions, which are some of the most rural parts of the state, have limited resources to fight cancer. Without these resources, screening to detect cancer in early stages, when cancer is more easily treated, is much more difficult. Also, care after diagnosis is less likely to be effective since facilities are harder to reach, which is compounded if the cancer has been diagnosed at a later stage. This is not a new pattern. When comparing the 1994-98 unadjusted county death rates to the 1984-88 ones, the same regions and many of the same counties have higher than average mortality rates. Comparisons of the age-adjusted rates do not change this pattern. Counties in the northeastern part of the state have especially high cancer death rates (Figure 4.D).

Cancer in Special Populations

Cancer in Minorities

Cancer does not occur among all groups of individuals at the same rate. Whites comprise 79 percent of North Carolinians; all other racial groups are considered minorities. Blacks represent the largest minority population in North Carolina (although there are sizable numbers of American Indians, Asians, and Hispanics).¹

In North Carolina in 1994 through 1998, cancer was the second leading cause of death for minority males and females, with age-adjusted death rates of 382.6 and 192.1 per 100,000 population respectively.² National data show that during the 1990s, mortality rates decreased among whites, African Americans, and Hispanics; remained stable among Asian/Pacific Islanders; and increased slightly among American Indians. African-American women are more likely to die of breast and colon and rectum cancer than are women of any other racial and ethnic group. African-American men have the highest mortality rates of colon and rectum, lung and bronchus, and prostate cancer. African American men are more than twice as likely to die of prostate cancer than men of other racial and ethnic groups.³

In 1998, the five leading contributors to cancer mortality among minority males in North Carolina were: lung, prostate, colorectal, pancreas, and stomach. For minority females, breast, lung, colorectal, pancreas, and ovarian were the five leading causes of cancer deaths.

Rural Populations

Roughly one-half of all North Carolinians live in rural settings. Citizens who live in rural areas, such as Appalachia, may have less access to state-of-the-art cancer care because of their isolated residence. However, the cancer centers of the state are making efforts to reach rural citizens with the latest cancer screening and treatment services. Several medical schools in the state have research programs directed at improving services to rural areas. In addition, the National Cancer Institute has developed special programs, such as the National Appalachian Leadership Initiative in Cancer, specifically aimed to reach this population.

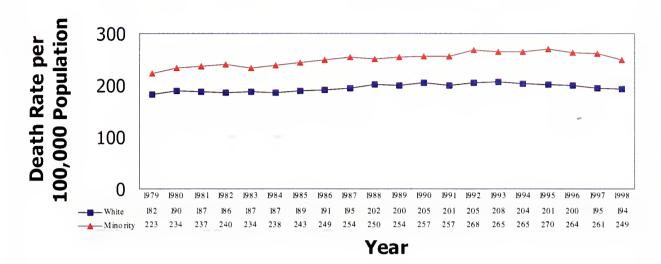

Other factors that may make rural populations more susceptible to cancer include different cultural or nutritional patterns and specific occupational risks such as exposure to pesticides associated with farming.

Cancer in Children

An estimated 1,600 cancer deaths are expected to occur among children ages 0-14 in 1999 in the United States, 45 in North Carolina. Despite its rarity and the fact that cancer mortality rates among children have declined 57 percent since the early 1970s, cancer is still the chief cause of death by disease in children under age 15 (deaths from injury are the highest). Approximately one-third of cancer deaths among children are from leukemia.

Cancer of the Colon & Rectum

Introduction

In 1998, a total of 1,517 North Carolinians died of colorectal cancer. This accounted for 9.9 percent of the state's total cancer deaths and 2.2 percent of all resident deaths. The 1998 ageadjusted mortality rate for colon and rectal cancer was 20.4 deaths per 100,000 population. During the five-year period 1994-1998, colon and rectum cancer ranked second among cancer deaths in North Carolina. During this same time period, colon and rectum cancer was among the top ten leading causes of death in North Carolina.

Differentials and Trends

The five-year age-adjusted mortality rate during 1994-1998 was 4.5 percent lower than the 1984-1988 rate. During this time period (1994-1998), minority males had the highest age-adjusted mortality rate of 31.7 deaths per 100,000 population followed by minority females at 25.2 deaths per 100,000 population. During this same time period, white females experienced the lowest age-adjusted mortality rate of 16.9 deaths per 100,000 population, while white males had a rate of 24.4 deaths per 100,000 population.

There is a wide sex differential in mortality for colorectal cancer. During 1994-1998, North Carolina's age-adjusted death rate was 44.4 percent higher for white males than for white females and 25.8 percent higher for minority males than for minority females. There is also a sizeable difference in age-adjusted death rates for racial groups. The 1994-1998 minority male rate was 29.9 percent higher than that for white males, while the minority female rate was 49.1 percent higher than the rate for white females.

In North Carolina, colorectal cancer deaths do not generally occur prior to age 45, with the colorectal cancer mortality rate peaking at ages 75+. The same is true for colorectal cancer incidence rates for North Carolina.

Colorectal cancer is the third most common malignancy in terms of new cases and deaths among men and women in the United States. The incidence rates for colorectal cancer have declined noticeably in the 1990's. The risk of developing colorectal cancer increases with age in men and women; however, at all ages, men are more likely to develop colorectal cancer than women. Men are also more likely to die from colorectal cancer than women.¹ Among North Carolina residents, there will be a projected 4,350 new colorectal cases in 1999.²

When colorectal cancer is detected in an early, local stage, the 5-year relative survival rate is 90 percent. After the cancer has spread regionally to involve adjacent organs or lymph nodes, the survival rate drops to 65 percent, while the rate for persons with distant metastases is around 8 percent. In North Carolina, approximately 35 percent of colorectal cases are diagnosed at the early stage.

Risk Factors

Inadequate nutrition is thought to be one of the greatest risk factors for developing colorectal cancer. While there is no recognized way to prevent colorectal cancer, it is thought that people can reduce their risk by eating a nutritious diet – particularly one that is low in fat and high in fiber. Dietary factors that are thought to play a protective role against the development of colorectal cancer include consuming high-fiber foods (fruits, vegetables, beans, legumes, and grains), cruciferous vegetables (cabbage, broccoli, cauliflower, and brussels sprouts), and vitamins A and C.³

Other risk factors that have been associated with an increased risk of colorectal cancer are physical inactivity and a family history of colorectal cancer or polyps.⁴

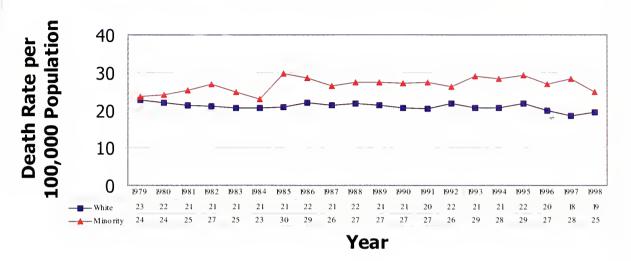

Like many other cancers, failure to have timely and appropriate screening also increases the risk of colorectal cancer death. It is recommended that beginning at age 50, men and women have cancer screening tests performed such as: digital rectal examination, fecal occult blood test, sigmoidoscopy, colonscopy, or double-contrast barium enema. These tests have resulted in a reduction in the number of deaths from colorectal cancer, by detecting and removing adenomatous polyps before these become cancers or by detecting and removing early stage colorectal cancers when the disease is still highly curable. However, a larger fraction of colorectal cancers could be prevented by appropriate modifications in diet and the adoption of regular physical activity.

Geographic Patterns

As shown in the unadjusted mortality rate map, higher mortality rates tend to be found in the northeastern part of North Carolina. The high unadjusted mortality rates found in the northeast are especially evident in counties such as Northampton, Hertford, Bertie, Chowan, and Gates. Ageadjusted colorectal cancer mortality rates were also higher in the northeast during the five-year period (1994-1998). Higher mortality rates in this region could be associated with poor screening (screening at later stages) and insufficient access to health care in this region compared with other parts of the state.

Cancer of the Trachea, Bronchus, & Lung

Introduction

Lung cancer continues to be the leading cause of cancer death for both men and women in the United States. In 1999, an estimated 160,000 people (mostly ages 50 and over) died in the United States of lung cancer: over 94,000 men and about 66,000 women, more deaths than from breast, prostate, and colorectal cancer combined.¹

Differentials and Trends

In 1998 a total of 4,692 North Carolinians died from lung cancer. This accounted for 30.6 percent of the state's cancer deaths and 6.9 percent of all deaths. Although lung cancer has long been the leading cause of cancer death among men, it became the leading cause of cancer death among women in North Carolina in 1990, exceeding breast cancer. In North Carolina, the age-adjusted mortality rate in 1994-1998 was 62.6 per 100,000 population. This represented a 14 percent increase over the 1984-88 rate and 2 percent increase over the 1989-93 mortality rate.

In every ethnic group, men have much higher lung cancer incidence and mortality rates than women. In 1993-1997, North Carolina minority males had the highest age-adjusted incidence rate followed by white males, white females, and minority females. African-American men have the highest lung cancer incidence and mortality rates. The American Cancer Society estimates approximately 171,600 new cases of lung cancer will be diagnosed in the United States in 1999. That is about 13 percent of all newly diagnosed cancers.¹ North Carolina projects 5,295 new lung cancer cases in 1999. The incidence and mortality rates, which until recently had been increasing steadily for both sexes, are now decreasing among men but continue to increase among women. This decline in lung cancer mortality represents more than half of the overall drop in cancer mortality among men over the past several years. North Carolina incidence rates are quite similar to those of the nation at large.

Early detection is very difficult because symptoms often do not appear until the disease is in an advanced stage. For those who stop smoking when pre-cancerous changes are found, damaged lung tissue often returns to normal. Chest x-ray, analysis of cells contained in sputum, and fiberoptic examination of the bronchial passage assist diagnosis. Warning signals include persistent cough, sputum streaked with blood, chest pain, and recurring pneumonia or bronchitis.

The one-year relative survival rate for lung cancer has increased from 32 percent in 1973 to 41 percent in 1996, largely due to improvements in surgical techniques. The 5-year survival rate for lung cancer is only 14 percent in all patients for all stages combined. For African Americans diagnosed during 1989-1995, the 5-year survival rate was only 11 percent, compared to 14 percent for whites. The survival rate is 49 percent for cases detected early when the disease is still localized, but only 19 percent of lung cancers in North Carolina residents are discovered early. Overall, lung cancer 5-year relative survival rates are very low. ²

Lung cancer is the leading cause of cancer death in African Americans, and is expected to cause 10,500 deaths in men and 6,000 deaths in women in 1999 in the United States. African-American men have had consistently high lung cancer incidence and mortality rates since the 1970's. However, during 1995-1996, lung cancer death rates in African-American men decreased on average 1.8

percent per year while rates in women appeared to be increasing slightly (0.2 percent per year). Mortality and incidence rates from lung cancer are higher for African-American men than for white men, even though African-American men begin smoking at an older age and smoke fewer cigarettes per day.³

Risk Factors

Eighty-seven percent of lung cancer cases are smoking-related.⁴ In past decades, cigarette smoking was very common among United States men. In 1955, nearly 60 percent of men were smokers. By the end of the 1960s, however, male smoking had dropped to less than 45 percent and this trend continued over the next two decades. As a result of this temporal pattern in smoking, and the lag time reflecting the carcinogenic process, lung cancer mortality among men peaked in the early 1990s. The subsequent decline in lung cancer mortality among men reflects the success of tobacco control efforts over the past three decades, resulting in decreased smoking rates among men over the last 30 years. However, the smoking patterns of women lag behind those of men. As a result, the lung cancer mortality rates are still rising among women.² Smoking among teens and young adults has increased in recent years in North Carolina⁵ and this could result in higher lung cancer death rates in the future.

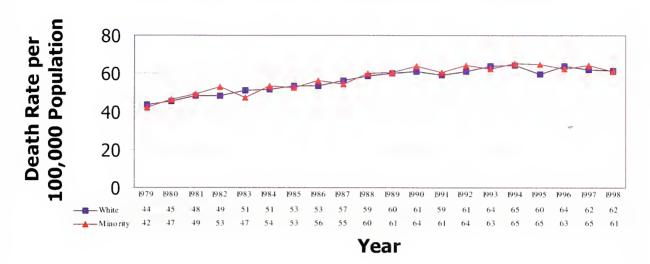

While cigarette smoking is the predominant risk factor for lung cancer, passive exposure to cigarette smoke increases the risk for nonsmokers. Other risk factors include exposure to certain industrial substances (such as arsenic); some organic chemicals; radioactive gas; asbestos; radiation exposure from occupational, medical, and environmental sources; air pollution; and tuberculosis.⁴

Geographic Patterns

During 1994-1998, residents of eastern North Carolina experienced generally higher lung cancer mortality than other parts of the state (Figures 6.C and 6.D) with moderate rates for some contiguous counties. Users should consult these maps to ascertain a county's relative level of unadjusted and age-adjusted mortality from lung cancer.

Cancer of the Female Breast

Introduction

Breast cancer is the most frequently occurring cancer in women, both in North Carolina and the United States. The American Cancer Society estimates 175,000 new invasive cases of breast cancer are expected to occur among women in the United States during 1999 with about 1,300 newly diagnosed cases of breast cancer expected in men for 1999.¹ The North Carolina Central Cancer Registry estimates a projected 5,660 new breast cancer cases among North Carolina women in 1999.

Differentials and Trends

According to the most recent SEER (U.S.) data (1973-1996), female breast cancer incidence rates among white females increased until 1987 and declined moderately thereafter. Rates for African-American women peaked in 1992 for women over age fifty and in 1991 for women under age fifty. Incidence rates for African-American women under age 50 have declined moderately since 1991, whereas rates for African-American women over 50 have remained relatively constant since 1992.

After increasing about 4 percent per year in the 1980s, breast cancer incidence rates in women leveled off in the 1990s. The incidence rate of female breast cancer was highest among white women and lowest among American-Indian women, yet African-American women were more likely to die of breast cancer than women of any other racial/ethnic group.

In 1998 there were 1,163 deaths from female breast cancer among North Carolinians. The number of deaths has remained stable since 1990. With breast cancer as the second major cause of cancer death among women, this accounted for 7.6 percent of the state's cancer deaths and 1.7 percent of all deaths. Based on North Carolina data from 1990-1997, about 65 percent of breast cancers were diagnosed at the local or in-situ stages.

United States mortality rates have declined over the past 10 years with noticeable decreases in younger women (both white and African-American), and this is attributed to earlier detection and improved treatment. An estimated 43,400 deaths are predicted nationally for 1999, but that estimate could prove to be too high if this trend continues. These data also indicate that while female breast cancer mortality rates for whites over age fifty declined over the past ten years, rates for African-American women over age 50 increased until 1990 and have been relatively stable since then. In North Carolina, the overall 5-year age-adjusted female breast cancer mortality rate (1994 -1998) declined by 9.2 percent from the 1984-1988 rate (from 31.5 per 100,000 females to 28.6).

The five-year survival rate for localized (early stage) breast cancer increased from 72 percent in the 1940's to 97 percent today. If the breast cancer was in situ (not invasive), the survival rate approaches 100 percent. If the cancer has spread regionally, the survival rate is 77 percent; and for women with distant metastases, the survival rate is 20 percent. Survival after a diagnosis of breast cancer declines beyond five years. Seventy percent of women diagnosed with breast cancer survive ten years, and 56 percent survive 15 years.²

Risk Factors

Approximately one in eight women will develop breast cancer sometime during their life. Breast cancer risk increases with age, with rates greatest for women over the age of 50. Several risk factors for breast cancer have been consistently identified. A personal or family history of breast cancer is the most established factor and familial risk is now being associated with specific gene mutations or oncogenes. Histories of ovarian or endometrial cancer are also known to be associated with increased cancer risk. Increased risk for breast cancer has been associated with first full-term pregnancy after age 30, and also with early menarche and late menopause. Obesity, heavy alcohol use, high-fat diets, and estrogen replacement therapy have been suggested as possible risk factors for breast cancer. A majority of women have one or more of these risk factors for breast cancer.

Geographic Patterns

The 1994-1998 period demonstrated a considerable variability among the counties (Figures 7.B and 7.C). The age-adjusted rates show generally higher rates in the eastern counties, likely due to higher concentration of African Americans in these counties. Users should consult these maps to ascertain a county's relative level of unadjusted and age-adjusted mortality from female breast cancer.

Cancer of the Prostate

Introduction

Prostate cancer is a major cause of morbidity and mortality among males in the United States, with nearly one in six men developing the disease during his lifetime. In North Carolina during 1999 alone, an estimated 5,100 new cases were diagnosed. In 1998, a total of 983 North Carolina men died of prostate cancer. This accounted for 15 percent of the state's male cancer deaths (6.5 percent of all cancer deaths) and three percent of all male deaths (1.5 percent of all deaths). The prostate cancer mortality rate in North Carolina in 1998 was 26.9 deaths per 100,000 resident men.

Differentials and Trends

The five-year age-adjusted mortality rate for 1994-98 represented an 8 percent decline from the preceding five-year period (1989-93). With the advent of better diagnostic tools in the early 1990's, the number of detected cases of prostate cancer has increased, while the death rate has declined.²

The death rate for this disease changes dramatically with age, increasing over sixty-fold between ages 50 and 75. For ages 80-84, the rate is 464 deaths per 100,000 male population and peaks at over 800 at ages 85 and older.³

Prostate cancer is much higher in minorities than in whites. In fact, the age-adjusted mortality rate for minorities across the state is about 2.5 times that of whites; this pattern mirrors national data.³

Risk Factors

The incidence of prostate cancer increases with age (especially after age 60). Persons with a family history of prostate cancer have a two-and-a-half times higher risk of developing prostate cancer. Unfortunately little else is known about the risk factors for prostate cancer. However, fat intake is specifically being studied by North Carolina researchers; differences in the metabolism of fatty acids between blacks and whites is the research focus.⁴

As is the case with many types of cancer, failure to have timely and appropriate screening also puts men at increased risk of prostate cancer mortality. The American Cancer Society recommends that both the Digital Rectal Exam (DRE) and Prostate-Specific Antigen (PSA) blood test be performed annually.⁴ However, other agencies (e.g. National Cancer Institute) do not support the use of PSA screening as of yet.⁵ With these controversies in standards of care, it is more difficult for patients and physicians to determine proper screening protocols.

Geographic Patterns

As shown in Figure 8.C, one can see that the eastern portion of the state has higher age-adjusted mortality rates. However, this geographic pattern is probably due primarily to higher percentages of minority persons in the eastern counties, and minority males are significantly more likely to die from prostate cancer than white males.

Acquired Immune Deficiency Syndrome

Introduction

In North Carolina, acquired immune deficiency syndrome (AIDS) accounted for 432 deaths in 1998, resulting in a rate of 5.7 AIDS deaths per 100,000 population. Since 1996, the number of North Carolina residents who have died from AIDS has dropped significantly to the point where AIDS is no longer ranked among the ten leading causes of death in the state. AIDS deaths have also dropped in ranking for each age and race group.

Differentials and Trends

Consistent with national trends^{1,2} the North Carolina AIDS death rate began a period of decline in 1996, dropping 19.9 percent from 1995. The rate decreased 42.5 percent from 1996 to 1997 and decreased 12.3 percent from 1997 to 1998. Although there has been a substantial decrease in the rate for the three-year period, the rate of decrease slowed from 1997 to 1998. This slowing of the rate of decline was also consistent with the national trend.²

In the United States, the demographics of HIV infection and AIDS have changed since the first cases were reported in 1981. Although homosexual men represented the largest demographic group in the early years of the epidemic, new cases of HIV infection are primarily the result of injection-drug use and heterosexual contact. As a result, minorities are disproportionately represented and the number of HIV cases among women is increasing.³ North Carolina death rates reflect this pattern.

North Carolina AIDS data for 1998 showed that 78.7 percent of AIDS decedents were of a racial minority, 71.5 percent were male, and 69.0 percent were between the ages of 25 and 44. These disparities between demographic groups were also reflected by race and sex-specific age-adjusted death rates. In 1998, the minority rate was 19.7 and the white rate was 1.6. The age-adjusted death rate for males was 8.3 and the rate for females was 3.2. Comparing age-adjusted rates across race and sex groups, all age-adjusted rates decreased from 1997 to 1998 with the exception of the rate for females. The rate for females increased from 3.1 to 3.2.

Closer examination of AIDS deaths within specific race-sex groups revealed that AIDS disproportionately affected minority women and men. The 1994-1998 age-adjusted death rate was 0.7 for white females and 14.3 for minority females. For white males it was 7.3 and for minority males it was 50.3.

Unlike other cause-specific deaths reported in this issue, a twenty-year description of mortality trends for AIDS is not possible. AIDS deaths have only been recorded since 1987. Prior to 1987, AIDS deaths were coded as "deficiency of cell-mediated immunity," which could also include conditions other than AIDS. Beginning in 1987, AIDS deaths were recorded under ICD-9 codes 042-044. Five-year age-adjusted death rates show an increase from 7.9 deaths per 100,000 population in 1989-1993 to 10.1 deaths per 100,000 population in 1994-1998, representing a 27.8 percent increase across the two five-year periods. Although comparisons between the two five-year periods reflect a large increase in the rate of AIDS deaths, single-year death rates reflect a sharp decline from 1996 through 1998.

Risk Factors

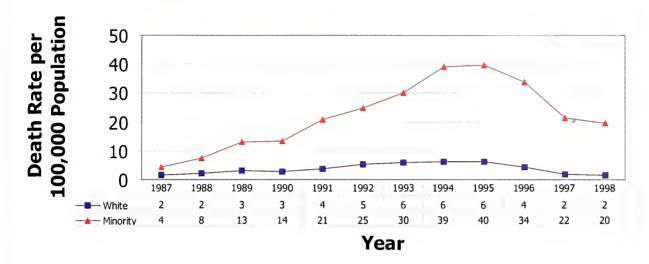

The sharp decreases in the death rates between 1996 and 1998 in the United States have been attributed to a number of factors. These factors include improved prophylaxis against opportunistic infections, improved treatment, a growing experience among health professionals in caring for HIV-infected patients, improved access to health care, prevention efforts, and the fact that a substantial proportion of persons with high-risk behavior are already inflected.³ Moreover, "...the most influential factor has clearly been the increased use of anti-HIV drugs, generally administered in combinations of three or more agents and usually including a protease inhibitor".³ A slower decline in the rate from 1996 to 1998 may indicate that much of the benefit of the new drug therapies has been realized.⁴

Geographic Patterns

The geographic distribution of AIDS mortality is presented in two maps. Figure 9.C shows the distribution of unadjusted death rates for 1994-1998 and Figure 9.D shows the distribution of age-adjusted AIDS rates for 1994-1998. In general, both maps show the same spatial distribution. Eastern North Carolina is characterized by higher AIDS death rates with high rates also in Mecklenburg County. A larger minority population in the eastern part of the state may primarily explain these geographic differences in rates.

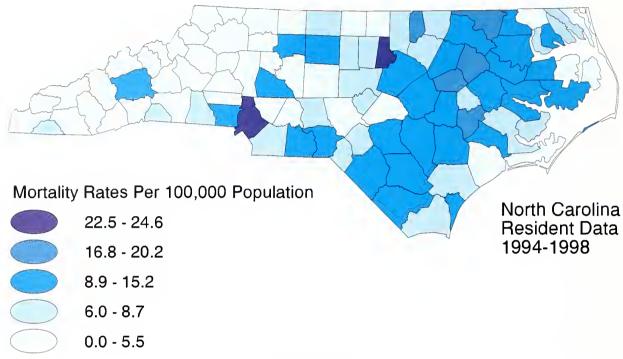

Figure 9.C

Acquired Immune Deficiency Syndrome

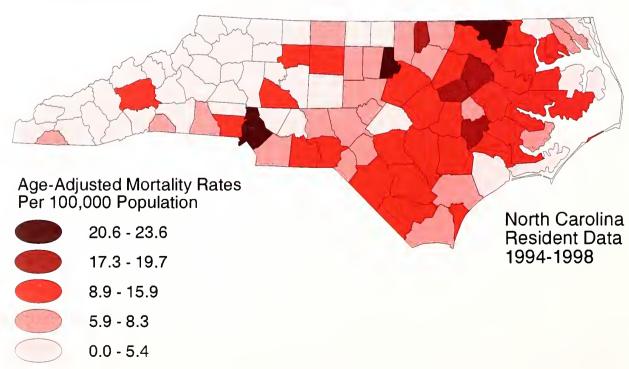

Figure 9.D

Septicemia

Introduction

Septicemia, sometimes called "blood poisoning," is a disease in which the blood is the site of bacterial growth as well as the means of transportation of infection. Because blood is the growth medium, the spread of septicemia is very rapid, making it an extremely dangerous disease. Septicemia is often caused by infection from bacterias such as e-coli, bacteriodes, salmonella, or streptococcus.^{1,2,3}

Differentials and Trends

In 1998, septicemia was ranked as the tenth leading cause of death in North Carolina. A total of 789 residents died from septicemia. This figure represents approximately one percent of all deaths in the state. Mortality rates for septicemia increased consistently from 1979-1987, then dropped significantly in 1988. From 1988 to 1997, the age-adjusted rate of death due to septicemia remained between 9.1 and 10.2 per 100,000 population, then the rate rose to 10.9 in 1998.

During 1994-1998 the number of deaths caused by septicemia was 3,372 with an age-adjusted death rate of 9.8. This statistic reflects a decrease from the age-adjusted death rate of 10.7 during 1984-1988. The age-adjusted death rates for each race-sex group are as follows: white males, 8.9; minority males, 19.6; white females, 7.7; and minority females, 15.2.

Risk Factors

Primarily at risk for acquiring septicemia are people whose health is already compromised by a preexisting health problem (such as AIDS, cancer, cirrhosis, or diabetes) or by recent surgical or medical procedures (i.e. central catheterization, parenteral nutrition). It often occurs among people already admitted to the hospital for the treatment of other conditions.³

Age also appears to be a risk factor for septicemia. Both the very young and the elderly appear to be at greatest risk for septicemia death in North Carolina.^{3,4} In 1998, this disease was ranked as the sixth leading cause of death for children less than one year old and the seventh leading cause of death for those ages one through four years of age. In the same year, for individuals ages 65 and over, septicemia is ranked as the ninth leading cause of death.

Males appear to be more likely to develop septicemia than females. According to recent research, males are more likely to develop opportunistic infections following surgery for trauma than females. As shown in Figure 10.B, in North Carolina from 1979-1998, males had an age-adjusted septicemia mortality rate that was slightly higher than that for females.

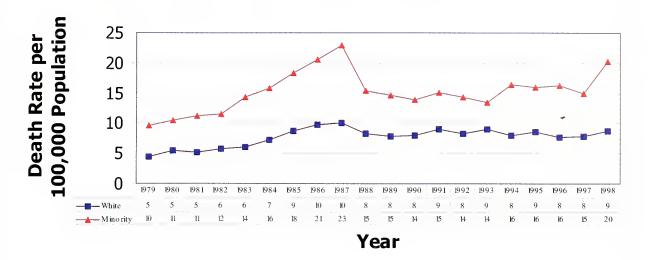

Minorities have higher mortality from septicemia. From 1979-1998, age adjusted mortality rates for septicemia were consistently higher for minorities than for whites in North Carolina (refer to Figure 10.A).

Geographic Patterns

Unadjusted and age-adjusted death rates for septicemia (Figures 10.C and 10.D) reveal that septicemia mortality is higher in North Carolina's eastern and western counties. The Piedmont region has a lower rate of septicemia deaths.

Septicemia

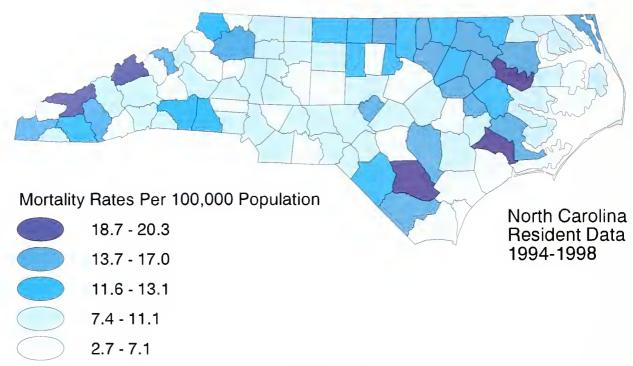

Figure 10.C

Septicemia

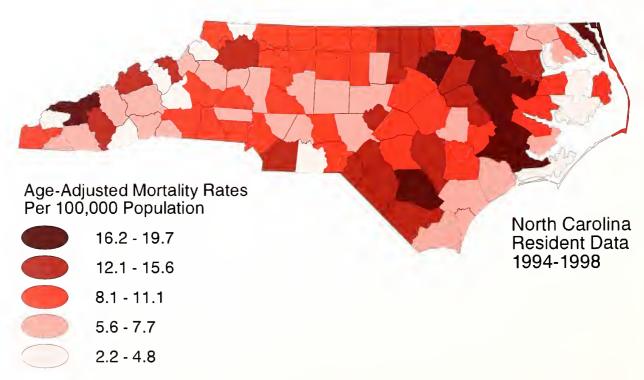

Figure 10.D

Diabetes Mellitus

Introduction

Diabetes mellitus is a disease characterized by high levels of blood glucose resulting from defects in insulin secretion, insulin action, or both. Diabetes is classified into two main types: Type 1 and Type 2. Type 1 diabetes (insulin-dependent) affects five to ten percent of those with diabetes and most often occurs during childhood or adolescence. Type 2 diabetes (non-insulin-dependent) is the more common type, affecting ninety to ninety-five percent of those with diabetes. Even though the details of this disease have been known for a long time, the incidence of diabetes has gradually increased during this century.¹ Diabetes and its complications occur among Americans of all ages and racial/ethnic groups, however the elderly and certain racial/ethnic groups are more commonly affected by the disease.² It is estimated that approximately 18 percent of Americans ages 65 and over have diabetes.

During the past decade there has been a significant increase in the incidence of diabetes to such an extent that it is now considered to have reached epidemic proportions. It is a major public health problem and a leading cause of death and disability in the United States. According to the National Center for Health Statistics, 15.7 million people – about six percent of the population – have diabetes. Of these, approximately 10.3 million people have been diagnosed with diabetes and it is estimated that the rest harbor the syndromes of the disease but remain undiagnosed.

Diabetes mellitus is the fourth leading cause of death in the United States and a major cause of kidney, cerebrovascular, and heart disease.³ Adults with diabetes have heart disease death rates about two to four times as high as that of adults without diabetes. In addition, the risk of stroke is two to four times greater in people with diabetes. Diabetes is also the leading cause of end-stage renal disease, accounting for about 40 percent of new cases. Diabetes can cause other acute life-threatening events, such as diabetic ketoacidosis and coma. In addition, people with diabetes are more susceptible to and are more likely to die from other illnesses including pneumonia and influenza.⁴

Differentials and Trends

Diabetes is the sixth leading underlying cause of death in North Carolina – resulting in more than 1,900 deaths in 1998. Death rates have increased over time for all ages and races.

The death rate for diabetes was higher as a leading cause of death among males than among females. In 1998, age-adjusted diabetes death rates (based on diabetes as the underlying cause of death) were higher among minorities than among whites. For 1994-98, age-adjusted death rates per 100,000 were 53.5 for minority women; 16.8 for white women; 51.2 for minority men; and 22.8 for white men. The rate for minority males was 2.2 times that for white males, while the minority female rate was 3 times the white female rate.

The annual number of deaths for which diabetes was the underlying cause increased from 1,597 in 1994 to 1,963 in 1998. By 1998, the unadjusted diabetes death rate was 15 percent higher than in 1994 (26.0 per 100,000 vs. 22.6 per 100,000, respectively). The age-adjusted death rate increased from 16.7 in 1979-83 to 25.3 in 1994-98, a rise of more than 51 percent.

While diabetes is recorded as the underlying cause of death for nearly 2,000 deaths of North Carolinians per year, it is a significant contributing factor to several times as many deaths from other underlying causes, such as heart disease and stroke.

Risk Factors

Risk factors are less well defined for type 1 diabetes than for type 2 diabetes, but autoimmune, genetic, and environmental factors are involved in the development of this type of diabetes.

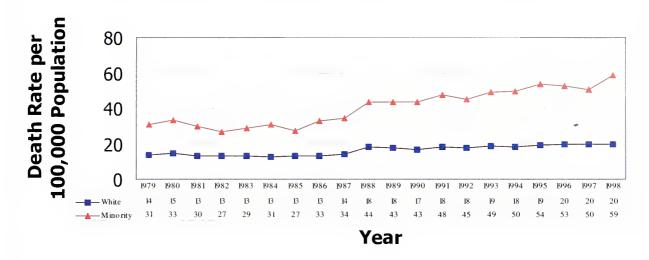

Risk factors for type 2 diabetes include older age, obesity, family history of diabetes, prior history of gestational diabetes, impaired glucose tolerance, physical inactivity, and race/ethnicity. African Americans, Hispanic/Latino Americans, American Indians, and some Asian Americans and Pacific Islanders are at particularly high risk for type 2 diabetes.⁴

Geographic Patterns

During 1994-1998 there was considerable variability among the counties with regard to unadjusted death rates for diabetes (Figure 11.C). This map shows that residents of the eastern and, to a lesser degree, western counties, are at relatively high risk of death from diabetes. Even after controlling for the impact of age (Figure 11.D) the eastern counties show higher diabetes mortality rates. This may be due to higher concentration of minorities in these counties.

Pneumonia and Influenza

Introduction

In 1998 a total of 2,688 North Carolinians died from pneumonia (viral or bacterial) or influenza. Pneumonia and influenza was the fifth leading cause of death in 1998 when ranked on the basis of unadjusted mortality rates. Race-sex-specific rankings reveal that during 1994-98 pneumonia and influenza was the fifth leading cause of death for white males, fifth for white females, ninth for minority males, and fifth for minority females. The 1997 North Carolina unadjusted mortality rate for pneumonia and influenza was nearly the same as the 1997 United States rate.¹

Differentials and Trends

The unadjusted mortality rate of 35.6 deaths per 100,000 population in 1998 was 8 percent higher than the 1997 rate of 33.1. A comparison of 1988 and 1998 reveals that the pneumonia and influenza rate rose 20 percent, from 29.7 to 35.6.

After adjusting for age (year 2000 standard) the upward trend in pneumonia and influenza mortality rates is dampened significantly. Only a three percent increase is noted when comparing 1988 and 1998 age-adjusted rates, suggesting that much of the increase in unadjusted rates is due to changes in age structure of the population. North Carolina's elderly population has grown more rapidly than the rest of its population, and is expected to increase by 70 percent in the next twenty years.²

The age-adjusted pneumonia and influenza death rate for 1994-98 was highest for minority males (55.1), followed by white males (47.9), white females (30.8), and minority females (26.8).

Risk Factors

Persons most at risk of dying from pneumonia or influenza are those over age 50, those with chronic diseases of the heart, liver, lungs, kidneys, or those with diabetes.³ The rate of pneumonia and influenza mortality increases with age, regardless of race or sex. In the period 1994-98 nearly 88 percent of such deaths were to persons 65 or older and pneumonia and influenza was the fifth leading cause of death in this age group.

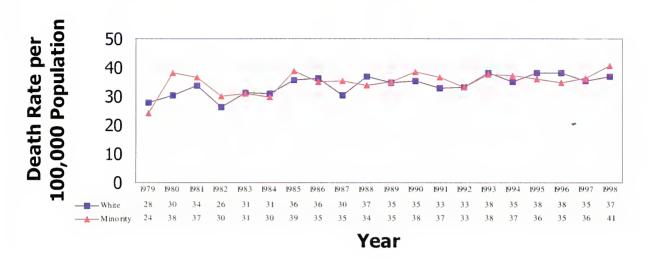

Respiratory infections in the form of pneumonia or pneumonitis are also quite common in the neonatal period and are a significant cause of morbidity and mortality in the newborn.⁴ Pneumonia and influenza is the sixth leading cause of death in infants.

Geographic Patterns

Figures 12.C and 12.D depict the county unadjusted and age-adjusted 1994-98 rates for pneumonia and influenza, As shown in Figure 12.C, most of the 100 North Carolina counties have relatively low unadjusted mortality rates. After adjusting for age, (see Figure 12.D), this pattern is not changed much. There is a relatively even geographic distribution of pneumonia and influenza death rates, with scattered higher-rate counties.

Chronic Obstructive Pulmonary Disease & Allied Conditions

Introduction

Chronic obstructive pulmonary disease (COPD) and its allied conditions refer to a group of chronic lung diseases which include conditions such as emphysema, chronic bronchitis, and asthma.

COPD is a chronic debilitating health problem for thousands of North Carolinians. Recent estimates by the American Lung Association reveal that there are approximately 119 cases of COPD per 1,000 North Carolina residents.¹ The incapacitating effects of severe lung problems greatly diminish the quality of life for individuals with COPD. Normal activities of daily life such as getting dressed or walking around the block may leave COPD sufferers out of breath. Many individuals with chronic lung disease eventually require full time oxygen support and recurrent hospitalization.^{2,3} In 1997, COPD was responsible for 27,723 hospitalizations and over \$190 million in total hospital charges in North Carolina. After years of diminished lung capacity, death from COPD is often accompanied by pneumonia, acute respiratory distress, cardiac arrhythmia, or pulmonary embolism.⁴

Differentials and Trends

In 1998 there were 3,200 deaths to COPD in North Carolina, making it the fourth leading cause of death in the state. Approximately five percent of North Carolina resident deaths are attributable to COPD each year. These figures mirror the latest national data where COPD ranked as the fourth leading cause of death in 1997. As shown in Table B, page 12, in 1998 COPD ranked eighth relative to other causes of death in terms of the number of years of life lost — with a total of 14,224 years of life lost for North Carolina residents.

Emphysema accounted for about 15 percent of all COPD mortality, claiming the lives of 493 North Carolinians in 1998. Another five percent (168) of COPD deaths were attributable to asthma. The rest of the COPD deaths were related to other allied lung conditions.

While mortality rates for cancer and heart disease have remained stable or declined over the past 20 years, COPD death rates have increased during the same time period. Whether we examine crude or age-adjusted mortality rates, deaths to COPD have been on the rise in North Carolina since 1979. Five year age-adjusted mortality rates for COPD have increased steadily from a low of 26.2 per 100,000 residents in 1979-1983 to a high of 41.9 deaths per 100,000 in 1994-1998, an increase of 60 percent.

North Carolina resident deaths from COPD are more common among certain demographic groups: the elderly, men, and whites. In 1998, 85 percent (2,727) of all North Carolina COPD deaths occurred among residents ages 65 and over. As shown in Figure 13.B, men were slightly more likely to die from COPD than women. In addition, unlike mortality patterns for most other diseases, COPD death rates are significantly higher for whites than for minorities. As shown in Figure 13.A, from 1979-1998, the age-adjusted mortality rate for whites was consistently higher than the rate for minorities in the state. Higher rates among men and whites are likely related to differential patterns of smoking behavior.⁵

Risk Factors

As with lung cancer, smoking is the most common risk factor associated with chronic obstructive pulmonary disease and allied conditions.^{1,2,5,6} The American Lung Association estimates that between 80 and 90 percent of all COPD cases are attributable to tobacco use.^{1,2}

Another factor believed to be associated with COPD is occupational exposure to chemical fumes and organic dusts. This type of job-related COPD is more common among individuals working in the mining and textile industries.^{6,7}

Genetics may also place some individuals at increased risk of developing particular types of COPD. For example, early-onset emphysema is caused by an inherited deficiency of a protein generated by the liver which helps to maintain proper lung functioning. It is estimated that between 50,000 and 100,000 Americans, mostly of northern European descent, currently have emphysema as a result of this protein deficiency.⁶

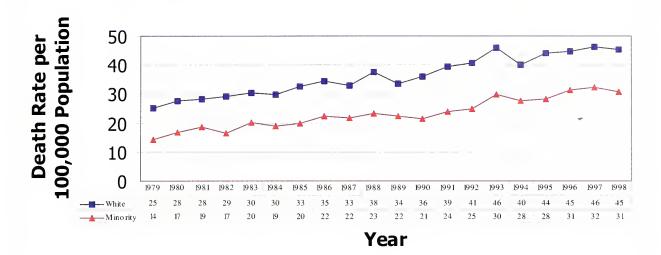

In addition, it is known that other factors including viral and bacterial infections, psychological stress, vigorous exercise, and exposure to air pollution, dust, and allergens may exacerbate pre-existing COPD problems and precipitate symptoms of respiratory distress.^{6,7}

Geographic Patterns

As shown in Figure 13.C, unadjusted mortality rates for COPD are highest in North Carolina's more mountainous, western counties. Western North Carolina counties tend to have an older population and a lower percentage of minorities. Also, some current research suggests that COPD mortality rates tend to increase with altitude and therefore may be more prevalent in mountainous regions.⁴ Although no obvious geographic patterns appear after adjusting for age (Figure 13.D), it appears that North Carolina's rural counties tend to have higher COPD mortality rates than more urban counties.

Chronic Liver Disease and Cirrhosis

Introduction

Nationally, the tenth leading cause of death in 1997 was chronic liver disease.¹ Chronic liver diseases include viral hepatitis and cirrhosis. Cirrhosis is a degenerative liver disease that may be caused by infections such as hepatitis or anything else that causes liver injury. Viruses, many poisons, and reactions to some drugs can cause liver damage, but cirrhosis is most commonly caused by alcoholism.² In North Carolina, 699 people died of these diseases in 1998. Of these, 539 were white and 160 were minority. The 1998 unadjusted death rate was 9.3 per 100,000 population.

Differentials and Trends

The trends for rates of death for the past 20 years indicate declining mortality risk from these diseases. Age-adjusted death rates for 1979-83, 1984-88, 1989-93, and 1994-98 were 12.5, 10.9, 10.9, and 9.5. The rate of minority deaths showed a stronger decline during the past decade, from 19.3 in 1988 to 10.8 in 1998. The rate of minority deaths was nearly twice that of whites in 1979, 23.4 versus 12.0. Age-adjusted death rates have declined for all groups during the 20-year period. The greatest drop in the minority death rate occurred between 1988 and 1998. During 1994-1998, age-adjusted rates were 19.0 for minority males, 12.3 for white males, 7.7 for minority females and 5.4 for white females. In 1998, the rates were much more similar for minorities (10.8) and whites (8.7) than in previous years. The rate of death for females is still about half that of males.

Risk Factors

Although mortality rates for chronic liver diseases and cirrhosis have declined in recent years, liver dysfunction is still a leading cause of death. It kills approximately 25,000 Americans each year. While these diseases are not entirely attributable to alcohol abuse, alcoholism is the most common cause. Some chronic liver conditions are related to inherited conditions, such as cystic fibrosis, Wilson's disease, hemochromatosis, and glycogen storage diseases or to chronic viral hepatitis.³ Declining deaths from cirrhosis in several Western countries have been linked to decreases in alcohol consumption⁴ and to increased treatments for alcoholism, but some studies found that geographic variability exists due to lag times for different populations.^{5,6,7}

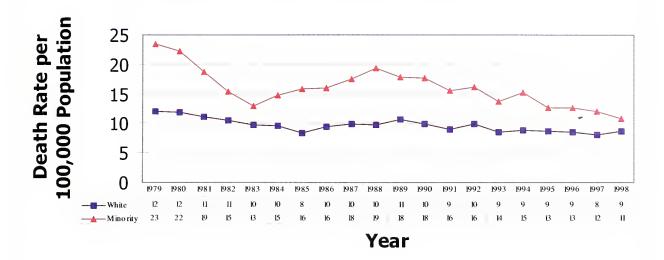

Geographic Patterns

Rural counties tend to have higher unadjusted and age-adjusted mortality rates, particularly in the northeastern part of the state. In Halifax and a few surrounding counties, the rates are particularly elevated.

Nephritis, Nephrosis, and Nephrotic Syndrome

Introduction

Nephritis, nephrosis, and nephrotic syndrome are diseases associated with the kidney. Nephritis is kidney failure regardless of the causal agent.¹ It manifests itself as inflammation of the kidney. Nephrosis and nephrotic syndrome present themselves as proteinuria, a condition in which excessive amounts of protein are excreted in the urine.² Clinical considerations include the underlying renal pathology, systemic hypertension, the magnitude and duration of proteinuria, and the degree of functional renal deterioration.³

Differentials and Trends

There were 702 deaths to North Carolina residents in 1998 attributed to nephritis/nephrosis. This resulted in a nephritis and nephrosis mortality rate of 9.3 deaths per 100,000 population. The age-adjusted death rate in North Carolina shows a decline from 1979 to 1988, followed by an increase. The 1979 rate of 10.0 declined to 8.3 in 1988, but has risen since then to a rate of 9.7 in 1998.

Of the 702 deaths to nephritis/nephrosis in North Carolina, the majority (87%) were reported for individuals ages 65 and over. Nephritis was the tenth leading cause of death among individuals in this age group. Looking at the differences by sex, we find that nephritis/nephrosis ranked as the tenth leading cause of death among women. Overall, nephritis/nephrosis was not one of the ten leading causes of death in North Carolina. Nephritis/nephrosis ranked as the ninth leading cause of death overall in 1997 for the United States.⁴

Risk Factors

While nephritis/nephrosis can kill at any age, perhaps the greatest risk factor for developing the disease is increased age. The elderly are at greater risk of nephritis/nephrosis mortality. As stated earlier, the vast majority of deaths from nephritis/nephrosis in North Carolina in 1998 were in persons ages 65 and older. In addition, individuals with other chronic diseases such as heart disease, hypertension, and diabetes are also at greater risk for nephritis/nephrosis mortality. Efforts aimed at controlling high blood pressure and diabetes coupled with proper nutrition would likely result in a reduction in nephritis and nephrosis deaths.

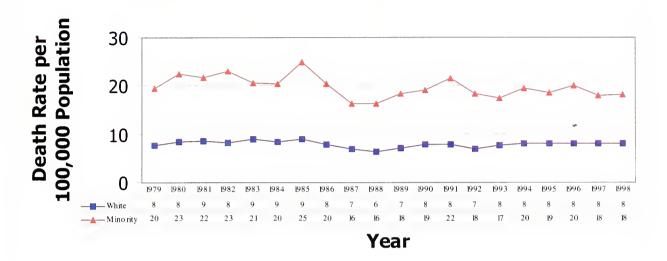

Geographic Patterns

The geographic distribution of mortality associated with nephritis/nephrosis is presented in Figures 15.C and 15.D. In general, the unadjusted and age-adjusted rates both show the same spatial distribution. It appears that nephritis mortality is relatively evenly distributed across the state.

Unintentional Injury (Motor Vehicle and Other)

Introduction

While heart disease and cancer consistently contribute to more deaths than other leading causes, injuries (both unintentional motor vehicle and all other unintentional injuries) represent another significant contributor to deaths of North Carolina residents. Since 1935 unintentional injuries have remained among the leading causes of death in North Carolina. In 1935, unintentional injuries represented 7.1 percent of total deaths. This percentage decreased to 4.7 percent in 1998. Unintentional injury deaths are amenable to reduction through public policy and effective education.

Injury deaths are coded according to the circumstances and behaviors that preceded them,² sometimes referred to as external causes of injury (thus E codes). Unintentional injury deaths refer to those deaths without a plan of inflicting personal harm. By ICD codes, unintentional injuries (E800-E949) have been subdivided into unintentional motor vehicle injuries (E810-E825) and all other unintentional injuries (E800-E807, E826-E949).

Differentials and Trends

In 1998, 3,218 North Carolinians died from unintentional injuries. Unintentional motor vehicle injuries contributed 1,632 deaths representing a rate of 21.6 deaths per 100,000 population; other unintentional injuries contributed 1,586 deaths representing a rate of 21.0 deaths per 100,000 population.

The 1998 rates represent an overall decrease during the past twenty years. In 1979 the age-adjusted death rate for unintentional motor vehicle injuries was 25.2 per 100,000 population. This rate decreased to 21.5 in 1998. The same pattern occurred with all other unintentional injuries, with a decrease in the age-adjusted rate from 29.7 in 1979 to 21.6 in 1998.

A striking difference, which has been the focus of current research, is the disparity in male and female unintentional motor vehicle injury death rates.³ In 1998 the age-adjusted male death rate of 30.8 was more than two times the female death rate of 13.1. The disparity has persisted since 1979 where the male rate (38.8) was more than three times the female rate (12.6).

These consistencies are mirrored at the national level. "Young men are two and one-half times as likely to die in motor vehicle accidents (than females) . . . even into their forties, men are more than twice as likely to die from motor vehicle accidents". Teens are over-represented among national motor vehicle deaths. While constituting 10 percent of the total population, 15 percent of motor vehicle deaths are among teenagers. This has led to increased efforts to reduce the disparities by discouraging risk-taking behavior prevalent in adolescent males. Graduated driver licensing is one such intervention strategy.

Large differences by sex are also observed within racial groups. The age-adjusted 1994-1998 minority male rate for all other unintentional injuries of 41.2 was more than three times the rate for minority females (13.9). For white males the 1994-98 age-adjusted rate was 29.1, compared to 13.1 for white females. Similar patterns are observed for motor vehicle injury deaths.

Unintentional injuries also contribute significantly to disability and hospitalization. In 1994, 4.5 million Americans were hospitalized and nearly 35 million visited emergency rooms because of

injuries. Medicaid expenses attributable to unintentional injuries were estimated at nearly \$80 billion. When linked to loss of income and productivity, the estimate increases to \$224 billion. Implementing additional programs such as workplace safety education and graduated driver licensing may help decrease the negative health impact of unintentional injuries.

Risk Factors

Unintentional motor vehicle injury deaths occur to drivers or pedestrians on public roads. Alcohol use has consistently been documented as a primary cause of motor vehicle deaths. The National Highway Transportation Safety Administration notes that the rate of alcohol-related motor vehicle deaths has declined from 1987 to 1996. This can be attributed to engineering improvements, and the passage/enforcement of laws limiting drinking to ages 21 and over.⁵

Unintentional injury deaths caused by firearm usage are closely related to lack of secure storage and gun safety training.⁶ In addition, it has been suggested that wearing highly visible clothing during hunting would decrease firearm injuries and deaths.⁷ Alcohol consumption is also a strong risk factor for all types of non-motor-vehicle unintentional injuries.

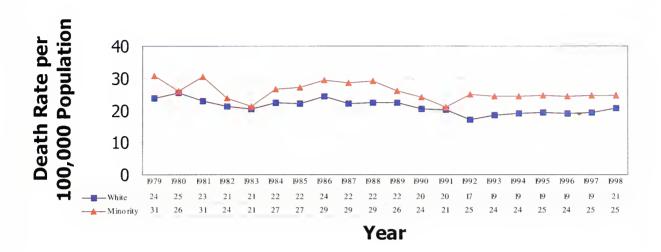

Geographic Patterns

There is a significant clustering of motor vehicle injury death rates in the eastern and southeastern North Carolina counties. Seven counties in the two highest age-adjusted rate levels are in the southeastern region.

There is no discernible geographic patterns of the unadjusted all other unintentional injury death rates. After age-adjustment, there are clusters of high-rate counties in the eastern and southeastern region of North Carolina, and also an area of elevated rates in northwestern North Carolina.

Suicide

Introduction

In 1998, suicide accounted for about one percent of all resident deaths in North Carolina. The unadjusted mortality rate from suicide was 11.2 per 100,000 population, representing 846 deaths to North Carolina residents in 1998. The highest suicide rate was observed among 75 to 84 year olds (19.7), while the next highest rate was found among 35 to 44 year olds (16.5). Furthermore, males were about four times as likely as females to commit suicide; out of a total of 846 suicide deaths in 1998, males accounted for 79.3 percent.

Suicide was the ninth leading cause of death in North Carolina in 1998. Suicide ranked fourth among 5 to 14 year olds, fourth among 15 to 24 year olds, fourth among 25 to 44 year olds, and ninth among 45 to 64 year olds.

Differentials and Trends

The age-adjusted suicide mortality rate for the state as a whole was 12.8 in 1979, increasing to a peak of 13.7 in 1982. After remaining steady for several years, the rates fell after 1990 to a low of 11.1 in 1998.

When considering large scale economic changes over the 20-year period, it is interesting to note that during periods of low job growth/high unemployment (early eighties), the suicide rate in North Carolina went up, while during periods of high job growth/low unemployment (mid-late nineties) annual suicide rates in the state have tended to decline.

Age-adjusted suicide death rates for 1994-98 differed significantly by race-sex group: 22.5 for white males, 12.9 for minority males, 5.5 for white females, and 1.9 for minority females.

Risk Factors

Epidemiological studies have found that both mental and addictive disorders, frequently in co-occurrence, account for over 90 percent of all completed suicides across all age groups.¹ Results from the National Longitudinal Alcohol Epidemiologic (NLAE) Survey revealed that major depression and alcohol dependence elevated the risk for suicidal ideation (recurrent thoughts of death or suicide) for men and women. With respect to gender differences, suicidal ideation increased among men with a past alcohol use disorder, a family history of alcoholism, and being unemployed. For women, suicidal ideation was elevated for those who had used drugs nonmedically and developed a drug use disorder in the past year. For both sexes, marriage was found to be protective.²

Our examination of North Carolina death certificates (1994-1998) showed that male suicide victims who were unemployed at the time of their death (n=415), were far more likely to be never married (78.3%) than married (10.1%). By contrast, among unemployed female suicide victims (n=304), only 25.3 percent were never married while 46.7 percent were married.

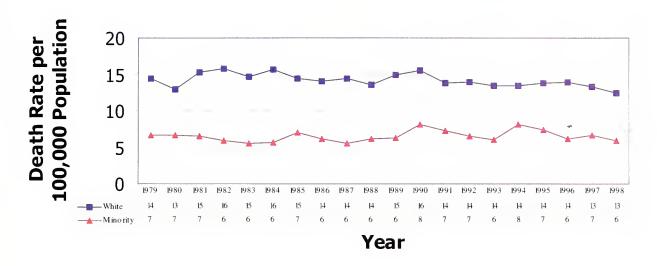

Geographic Analysis

The geographic patterns of 1994-98 unadjusted and age-adjusted suicide rates are depicted in Figures 18.C and 18.D respectively. Both maps show most counties with the highest rates to be

located in western North Carolina. This is probably associated in part with the fact that western North Carolina counties have a higher proportion of whites, where suicide death rates are higher³.

Homicide

Introduction

In 1998, there were 664 homicides in North Carolina, which represents about one percent of all deaths in the state. The overall unadjusted rate of death from homicide was 8.8 per 100,000 population in 1998.

Differentials and Trends

For all deaths in 1998, homicide is not one of the ten leading causes of death. However, that changes when different age, race, and sex categories are examined separately. For all age categories under 45 years old, homicide was one of the ten leading causes of death. For deaths of 15 to 24 year olds, homicide was the second most frequent cause of death with motor vehicle injuries being the first. The were 163 deaths due to homicide in this age group which represents 17 percent of all deaths of individuals 15 to 24 years old.

There are also differences in the leading causes of death by race and ethnicity. For blacks and American Indians, homicide is one of the top ten causes of death for 1998 but it is not for whites. Among blacks, 2.4 percent of all deaths are due to homicide, and 3.9 percent for American Indians. This compares to only one percent of all deaths in North Carolina for 1998. Hispanic deaths are also disproportionately due to homicide, at 14 percent of all deaths. Homicide is the second leading cause of death among Hispanics with motor vehicle injuries being the first.

During 1994-98, the group with the highest rate of homicide deaths was minority males between 15 and 24 years of age, where the rate was 74.7. This is 6.4 times higher than the rate of 11.7 for white males in the same age group. The next highest rate was 71.9 for minority males ages 25 to 34, whose white counterparts had a rate of 13.2. The homicide rates for minority females are not only higher than those of white females, but also exceed or equal those of white males in several age groups. The largest difference is found in the 25-34 age group where minority females had a homicide death rate of 18.6 compared to 13.2 for white males of the same age.

Over the past 20 years, the age-adjusted rate of homicide death in North Carolina has varied considerably. In 1979, the overall age-adjusted rate of death from homicide was 11.7. This rate declined over the next few years. From 1983 through 1988, the rate remained between 8.5 and 9.1. This trend reversed in 1989 when it increased to 10.2. This increase continued until a high of 12.5 was reached in 1991 when there were 889 deaths due to homicide. Between 1991 and 1994 the rate of deaths from homicide remained over 11 and then began to decrease in 1995 to a low of 8.6 in 1998.

Risk Factors

Looking at the rates of death by homicide over the past 20 years, there are certain demographic characteristics that have remained risk factors for being the victim of homicide. There are rather extreme disparities in the homicide rates by sex, race, and age. Males have consistently had rates three to four times as high as those of females. In the past twenty years, the age-adjusted rate of male deaths due to homicide has ranged from 12.9 in 1988 to 19.6 in 1991. There has been less variation in the rates for females. The lowest rate of female deaths to homicide was in 1998 when it was 3.9 and the highest rate was 5.8 in 1991.

The racial differences in homicide death rates are also large. The rate of death due to homicide for minorities is more than four times as high as that of whites. Over the past 20 years, there has been some fluctuation in the amount of difference. In the mid 1980's the age-adjusted rate of minority deaths was approximately 3.5 times as high as the white rate, with rates around 20 for minorities and 5.5 for whites. This difference increased in the early 1990's with minority rates in the upper twenties (27.1 to 29.6) which was 4.5 times the white rates for those years.

In 1995 handguns were the most frequent means of death in homicides. Firearms (all types) were used in 74 percent of the homicides. This represents an increase from 1988 when firearms were the means of death in 64 percent of homicide cases.

The medical examiner performs autopsies and blood alcohol tests on all deaths that are suspected homicides. Alcohol is involved in a significant percentage of all homicides. In approximately 40 percent of homicide deaths in 1995, alcohol was present in the victim. However, this varied by age group with those between 25 and 64 years old having alcohol present in almost 50 percent of the cases.¹

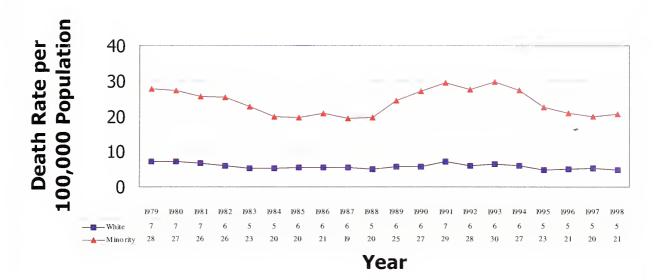

There has been much research about ways to reduce homicides. However, unlike deaths that are the result of a disease or other health problems, homicide involves many social issues. There has been much research showing that drug and alcohol abuse, poverty, and social isolation are related to homicides.^{2,3,4} A majority of homicides involve guns, and one study suggests that gun ownership increases your risk of being a victim of homicide in the home.⁵

Geographic Patterns

Maps depicting unadjusted and age-adjusted homicide rates are presented in Figures 19.C and 19.D. Higher unadjusted and age-adjusted homicide mortality rates cluster in the south central and the northeastern portions of the state. This may be related to the racial composition of these areas.

Infant Mortality

Introduction

Unlike other causes of death listed in this report, infant mortality (defined as death within the first year of life) includes deaths from all causes. Birth defects and complications related to preterm birth/low birth weight account for the vast majority of infant deaths in North Carolina. Although the infant mortality rate is not age-adjusted, it is often partitioned into two components: 1) neonatal mortality, which includes deaths under 28 days of age; and 2) postneonatal mortality, which includes deaths from 28 to 365 days of age.

In 1998 there were 1,037 infant deaths to North Carolina residents, accounting for 1.5 percent of all resident deaths in the state. Approximately 70 percent (n=723) of the infant deaths were among neonates, with the remaining 30 percent occurring during the postneonatal period. The overall infant mortality rate in 1998 was 9.3 deaths per 1,000 live births. The provisional 1998 United States rate was 7.0.1

Differentials and Trends

Since 1979 North Carolina's infant mortality rate has declined by almost 39 percent, from 15.2 to 9.3. About 60 percent of this decline occurred between 1979 and 1986. This was a period during which advancements in neonatal intensive care and the continuing development of the state's regionalized perinatal program led to substantial improvements in the survival of low birth weight infants and other critically ill newborns.²⁻⁴ In 1988, North Carolina's infant mortality rate of 12.6 placed the state 49th in the United States in infant mortality, prompting a concerted effort to improve services for pregnant women such as prenatal care and enhanced Medicaid coverage to 185 percent of the poverty level.⁵ Although the infant mortality rate continued a general pattern of decline over the next several years, since 1995 there has been no improvement in the rate in North Carolina while the United States infant mortality rate has continued a downward trend.⁶ A major factor contributing to the lack of improvement in North Carolina's infant mortality rate is the increasing rate of very preterm births, which has been on the rise since the late 1980's.

Risk Factors

Because infant mortality is often considered to be a barometer of the general health and well-being of a population, discussion of the major risk factors frequently focuses on socioeconomic indicators such as poverty, low education, young maternal age, and unintended pregnancy. In fact, the strongest direct risk factors for infant death are maternal medical conditions such as infection, hypertension, and diabetes; obstetrical complications such as vaginal bleeding, poor weight gain, and multiple gestation; and previous pregnancy history, including prior fetal or infant death. With disadvantaged populations tending to be at increased risk for many of these conditions, and to have generally poorer health status overall compared to other groups, the link between infant mortality and low socioeconomic status is clear.

A more perplexing issue is the association between race and infant mortality. Minority populations, and African Americans in particular, often experience infant mortality rates that are more than twice that of whites.⁶ Over the past twenty years the black-white disparity in infant mortality

has continued to increase and has grown to a 2.5-fold difference in 1998 (Figure 20.A). While poverty and other socioeconomic factors clearly play an important role in the high minority infant mortality rate, the fact that the racial disparity persists even after controlling for these factors suggests that the problem is considerably more complex than can be explained by poverty alone.⁷⁻⁹

Geographic Patterns

County infant mortality rates tend to be highest in the northeastern coastal plain (Figure 20.C). This pattern is due largely to the higher proportion of births to minorities in these counties, combined with the high rate of infant death among these groups as discussed above. Other issues, such as limited access to prenatal care and other preventive health services, may play a role in the high infant mortality rates in this predominantly rural region of the state.

Infant Deaths

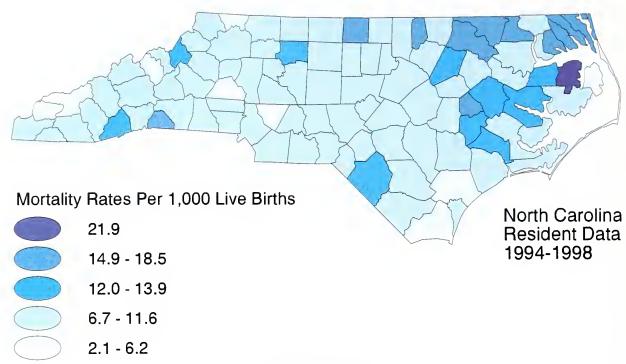

Figure 20.C

TECHNICAL NOTES

Computation of Death Rates

In this report, total mortality rates are expressed as resident deaths per 1,000 population. All cause-specific death rates are expressed as resident deaths per 100,000 population. Deaths are assigned to cause-of-death categories based on the underlying (or primary) cause of death from the death certificate. Appendix A describes the cause-of-death categories in terms of codes from the ninth revision of the International Classification of Diseases. All rates in Tables 1-19 use total population in the denominator except rates for the sex-specific cancer sites use male or female population in the denominator. Population bases for these rates were provided by the Office of State Planning in the Governor's Office. The infant mortality rates in Table 20 and Figures 20.A-20.C are computed as the number of resident deaths under one year of age per 1,000 resident live births.

Deaths in this report are assigned to place of residence. For deaths of people in long-term institutions (mental, penal, old age, orphan, nursing home, rest home, etc.), the institution is considered the usual residence if the decedent lived in the institution at least one year. College students and military personnel are considered residents of the college or military community.

The following definitions apply to the rates of this report:

Unadjusted Annual Death Rate: The annual death rates are computed as resident deaths per 1,000 or 100,000 population. These rates reflect an area's status according to the deaths during the given year.

Unadjusted 5-Year Death Rate: The average annual death rates are computed as average resident deaths per 1,000 or 100,000 average population. These multi-year rates are computed by summing the deaths for the five years, summing the population for the five years, dividing the former by the latter, and then multiplying the result by a constant (1,000 or 100,000). These rates give an area's status with respect to the deaths during the 5-year period and are shown in the first set of maps (e.g. Figures 1.C, 2.C).

Adjusted 5-Year Death Rate: The average annual age-adjusted rates are computed by the direct method. These rates are also expressed as deaths per 1,000 or 100,000 population and represent the rate that would be expected if the age composition of the state and each county's population were the same as that projected for the nation in the year 2000. However, the user should not compare an adjusted death rate to an unadjusted death rate. Also, adjusted rates for different time periods cannot be directly compared unless they were adjusted by the same standard population.

The age-adjusted rates in this 1998 edition of *Leading Causes of Death* involve a significant change from past editions. While the 1996-97 editions of this publication used the 1990 North Carolina population as a standard, this year the age-adjusted deaths rates are standardized using the projected United States 2000 population. **Therefore, the adjusted rates in this 1998 edition are not comparable to those in previous editions**. With this in mind, the 1998 edition includes five-year age-adjusted death rates, using the United States 2000 standard population, over a twenty year period (1979-1988) to allow for comparisons of the adjusted death rates over time. However, the second set of maps includes only the 1994-98 age-adjusted death rates (e.g., Figures 1.D, 2.D).

We have changed the standard population again to be consistent with the new practices of the National Center for Health Statistics. This will allow in the future direct comparisons of the state and county age-adjusted death rates for North Carolina to the published United States age-adjusted death rates.

In age-adjusting the death rates in this publication, 10 age groups are used to compute age-specific death rates for each geographic area and cause of death. These rates are then applied to the 2000 United States standard population by age: 0-4, 5-14, 15-24, 25-34, 35-44, 45-54, 55-64, 65-74, 75-84, and 85+. For details of the age adjustment process, refer to the Statistical Primer on age-adjusted rates in Appendix D.

For the maps, a clustering routine from the Statistical Analysis System (SAS) was used to group counties that are "most like each other" with respect to their unadjusted and their adjusted rate. These maps show five levels of death rates, where level one is the lowest rate interval and level five the highest.

A word of caution: Rates for sex-specific cancers (e.g., prostate) use male or female population in the denominator and therefore are not comparable to other rates. Therefore, in ranking the causes of cancer death by site one must use the observed <u>number</u> of deaths rather than the rates.

Interpretation of Death Rates

To assess a county's relative mortality during a 5-year period, both the unadjusted and the adjusted rate can be compared to the corresponding state rates for a particular cause of death. This, of course, should not be done if the county's unadjusted rate has fluctuated widely in recent years. The rate should represent a relatively stable situation. Then, the following alternative interpretations will apply:

Relative S Unadjusted Rate	Status Of Adjusted Rate	Interpretation of Unadjusted Rate
Low	Low	Low mortality is not due to age, other mortality conditions are favorable.
Low	High	Low mortality is due to favorable age distribution, other mortality conditions are unfavorable.
High	Low	High mortality is due to unfavorable age distribution, other mortality conditions are favorable.
High	High	High mortality is not due to age, other mortality conditions are unfavorable.

Caution:

In assessing the relative mortality of a county, be particularly aware of rates based on a small number of deaths (fewer than 20 deaths). In such cases, random fluctuation in the rate may render rate comparisons risky. The reader should read very carefully the next section entitled "Caution About Use of Rates."

Caution About Use of Rates

Small Number of Events:

Any death rate with a small number of deaths in the numerator will have substantial random variation over time (a large standard error). A good rule of thumb is that any rate based on fewer than 20 events in the numerator may be subject to serious random error. As such, extreme caution should be taken when making comparisons or assessing trends with rates calculated with fewer than 20 events. Many of the death rates in this report have numerators smaller than 20. For a detailed discussion of Problems with Rates Based on Small Numbers, refer to Statistical Primer No. 12 of the State Center for Health Statistics, available on our Web site (www.schs.state.nc.us/SCHS/) or by request to the Information Services Unit.

Adjusted Death Rates:

Unadjusted death rates are affected by the demographic composition of populations. As such, differences in demographic composition from one geographic area to another or from one point in time to another may hinder comparisons. The standardized adjustment of rates addresses this problem. The adjusted rate is a hypothetical rate computed in a way that reflects what the death rate would be in a particular geographic area, if the geographic area had the same age composition of the standard population. The measure, while useful for comparative purposes across time and geographic area, has no observable or descriptive value in and of itself. The adjusted rate provides opportunities for comparisons across time and geographic area as long as all rates that are to be compared share the same population standard and are adjusted for the same demographic categories.

Small Subpopulations:

As discussed above, adjusted rates in this 1998 edition of the *Leading Causes of Death* represent a change from previous editions. While the 1996 and 1997 editions used the 1990 North Carolina population as the standard in calculating age-adjusted death rates, the age-adjusted death rates in the 1998 edition are based on a projected United States 2000 population standard. Since the adjusted rates in this edition are not comparable to rates in earlier editions of this publication, five-year age-adjusted rates from 1979 through 1998 are included in each cause-of-death table so that the rates can be compared over time.

Beginning with the 1996 edition of *Leading Causes of Death*, age-adjusted rates rather than age-race-sex adjusted rates have been presented. This change was made because small age-race-sex populations may produce unstable age-race-sex adjusted rates. One death out of an estimated population of five, for example, would produce a death rate of 20,000 per 100,000 population. If this rate were applied to the appropriate age-race-sex group of the standard population, a very large number of expected deaths would result and the adjusted rate would be extremely high. On the other hand, zero deaths in several population groups may result in a very low age-race-sex adjusted rate.

Counties with a very small minority population, predominantly in western North Carolina, are particularly subject to extreme age-race-sex-adjusted rates (high or low) due to small age-race-sex-specific population groups. For example, in the 1995 *Leading Causes of Death*, Macon County was shown as having a 1991-1995 age-race-sex adjusted death rate for breast cancer of 64.6 compared to the adjusted state rate of 28.3. Further investigation showed that this very high adjusted rate was due to two breast cancer deaths in a very small age 55-64 minority female population group. When the 1991-95 breast cancer death rate was adjusted only for age, the Macon County rate was 30.4 compared to a North Carolina age-adjusted rate (1980 standard) of 25.6. Unusually high or low rates, therefore, may be biased due to small numbers. To eliminate these problems, the 1996 and subsequent editions of this publication report only age-adjusted rates. By dividing the deaths and population into 10 age groups rather than 40 age-race-sex groups in order to calculate an adjusted rate, the adjusted rates will be much more stable statistically. Also, age generally has a much stronger impact on mortality than race or sex, and therefore is the most important factor to adjust for.

Age-Adjusted Death Rates

by

Paul A. Buescher

Introduction

Mortality or death rates are often used as measures of health status for a population. Population-based incidence or morbidity data are available in North Carolina in a few areas such as cancer and certain communicable diseases, but for most chronic diseases we know only how many people died from the disease and not how many are living with it. Given the importance of data from death certificates in measuring the health of populations, it is important that valid comparisons of death rates are made. Many factors affect the risk of death, including age, race, gender, occupation, education, and income. By far the strongest of these factors affecting the risk of death is age. Populations often differ in age composition. A "young" population has a higher proportion of persons in the younger age groups, while an "old" population has a higher proportion in the older age groups. Therefore, it is often important to control for differences among the age distributions of populations when making comparisons among death rates to assess the relative risk of death. This Statistical Primer describes how age-adjusted death rates are calculated and discusses some related issues.

The methods for adjusting death rates for age that are shown here could also be applied to other characteristics of a population, such as income or gender, if it were considered desirable to adjust for such characteristics before comparing death rates. Also, disease incidence rates, birth rates, or other types of rates could be adjusted for age, or other factors, using the general approach presented here.

Crude and Age-specific Death Rates

A crude or unadjusted death rate is simply the number of deaths divided by the population at risk, often multiplied by some constant so that the result is not a fraction. For example, for Hertford County, North Carolina during the period 1991 through 1995, there were 1,336 deaths to residents of the county. To get an annualized death rate for this five-year period, the estimated mid-year resident population is summed over the five years. For Hertford County, the sum of the population of those five years is 112,419. The crude death rate is 1,336 divided by 112,419 which equals .01188. This is the average annual proportion who died during the period 1991-95 (slightly more than one percent). When multiplied by 1,000, which is a common multiplier for a death rate for all causes of death, the rate is 11.9 deaths per 1,000 population per year (see last row of Table 1). For death rates for specific causes of death, a multiplier of 100,000 is often used so that the rate is not less than 1.0. For smaller geographic areas or when using cause-specific death rates, it is often desirable to calculate multi-year death rates to decrease random variation in the rates due to small numbers of deaths in a single year. These multi-year death rates are essentially average annual rates.

Table 1
Age-Specific Death Rates for All Causes of Death
Hertford County, North Carolina Residents
1991-1995 Combined

	1 Number of	2 Sum of	3 Percentage	4 Age-Specific	5 Death Rates
Age Group	1991-95 Deaths	1991-95 Population	of Population by Age	Proportion Who Died	Per 1,000 Population
0-4	30	8,150	7.3	.00368	3.68

35-44	59	16,199	14.4	.00364	3.64
45-54	85	12,381	11.0	.00687	6.87
55-64	147	10,277	9.2	.01430	14.30
65-74	305	9,370	8.3	.03255	32.55
75-84	406	5,631	5.0	.07210	72.10
85+	244	1,829	1.6	.13341	133.41
Total	1,336	112,419	100.0	.01188	11.9

The crude death rate is a good measure of the overall magnitude of mortality in a population. If a population is old and has a high mortality rate as a result, then the crude rate is useful information for some purposes, such as planning for the delivery of health care services.

An age-specific death rate is simply a crude death rate for a specific age group. One can also calculate rates specific for race, gender, or other factors. Table 1 shows age-specific death rates

for Hertford County residents for the period 1991-95, with ten commonly-used age groupings. Note that the death rate for ages 0-4 is substantially higher than the death rates for the other younger age groups (primarily due to a high death rate during infancy); only at ages 45-54 does the death rate exceed that for ages 0-4. It can be immediately seen that the death rates are many times higher in the oldest age groups. Therefore, a geographic area or demographic group with an older population will automatically have a higher overall death rate just because of the age distribution. The main purpose of age-adjusting death rates is to control for differences in the age distribution of various populations before making mortality comparisons.

For some causes of death, such as injuries and AIDS, older persons do not have the highest death rates. But even in these cases it is important to standardize for age when comparing death rates across different populations, since some populations may have a higher proportion of persons in the age groups with the highest death rates.

Another Statistical Primer by the State Center for Health Statistics discusses the issue of random error in vital rates and presents formulas for quantifying this error and calculating confidence intervals around the measured rates. Those formulas are applicable to the crude and age-specific rates presented here, and to any simple or unadjusted rate. Random error may be substantial when a rate or percentage has a small number of events in the numerator (e.g. less than 20).

Age-adjusted Death Rates

Direct Method

The direct method of age adjustment is frequently used to compare the death rates of different populations, by controlling for differences in age distribution. The age-specific death rates of the population of interest (sometimes called the "study" population) are applied to the age distribution of a "standard" population in order to calculate "expected deaths." These are the deaths that would occur in the standard population IF the age-specific rates of the study population were in operation. These expected deaths for each age group are then summed and divided by the total standard population to arrive at the age-adjusted death rate. Stated another way, this is the death rate that the study population would have IF it had the same age distribution as the standard population.

Table 2 provides an example. The age-specific death rates for all causes of death for Hertford County are applied to the 1980 North Carolina population by age, which is used as the standard. (Any population could be used as the standard; the 1980 North Carolina population was chosen somewhat arbitrarily for purposes of illustration.) To generate the expected deaths in column 4, the rates shown in column 1 are converted to a proportion by moving the decimal point three places to the left and then multiplied by the standard population groups by age in column 2. The total expected deaths are then divided by the total standard population and the result multiplied by 1,000 to yield an age-adjusted death rate for Hertford County of 8.7. Usually it would not be necessary to show the age-specific death rates to two decimal places (false precision), but in this case the extra digits are needed to get a more accurate estimate of the number of expected deaths.

Table 2
Age-Adjustment by the Direct Method
Hertford County, North Carolina Residents
1991-1995 Combined; All Causes of Death

	1 Hertford County 1991-95 Age-Specific Death Rate	2 1980 N.C. Population	3 Percentage of Standard Population	4 Expected
Age Group	(per 1,000)	(Standard)	By Age	Deaths
0-4	3.68	404,560	6.9	1,489*
5-14	0.12	927,836	15.7	111
15-24	1.45	1,144,204	19.4	1,659
25-34	2.29	968,215	16.4	2,217
35-44	3.64	689,838	11.7	2,511
45-54	6.87	601,866	10.2	4,135
55-64	14.30	552,494	9.4	7,901
65-74	32.55	389,244	6.6	12,670
75-84	72.10	172,408	2.9	12,431
85+	133.41	45,956	0.8	6,131
Total	11.9	5,896,621	100.0	51,255
	(Crude Rate)			
	Age-Adju			
	Death Ra	te = $(51,25)$	55 ÷ 5,896,621) x 1,000	
		= 8.7		

This adjusted death rate is considerably lower than the crude death rate of 11.9. This is mainly because the percentages in the age groups 65 and older are substantially lower in the 1980 North Carolina standard population (column 3 of Table 2) than the same percentages in the 1991-95 Hertford County population (column 3 of Table 1). When the Hertford County age-specific death rates are adjusted to a younger standard population, the overall adjusted rate is lower.

The crude death rate for North Carolina for the 1991-95 period for all causes of death was 8.9, compared to the crude rate of 11.9 for Hertford County. The 1991-95 North Carolina death rate adjusted to the 1980 North Carolina age distribution is 7.4, compared to the age-adjusted rate of 8.7 for Hertford County. The difference in the crude rates between North Carolina and Hertford County is larger partly because Hertford County had an older population. The fact that the age-adjusted rate for Hertford County is still higher than that for North Carolina suggests that the 1991-95 age-specific death rates for Hertford County were generally higher than those for the state in 1991-95.

Ten age groups are often used for age adjustment of death rates. This provides enough detail to capture differences in the age distributions of the populations that are being compared, but not so

many age categories that the data are "spread too thin." For many years, the State Center for Health Statistics used 18 five-year age groups for age adjustment, but during the 1980's changed to ten age groups because the 18 categories often resulted in the numerators of the age-specific rates being very small, leading to unstable rates.

An alternate formula for computing the age-adjusted death rate by the direct method is simply to sum the products of the age-specific death rate and the proportion of the standard population in that age group across all ten age groups. This weighted sum is represented by the following formula:

Age-adjusted death rate =
$$\sum_{i=1}^{10} w_i p_i$$

where p_i is the age-specific mortality rate for age group i and w_i (or the weight) is the proportion of the standard population in age group i (move the decimal point of the percentages in column 3 of Table 2 two places to the left). The crude death rate can also be expressed as a weighted sum of the age-specific death rates and the proportions of the population by age, where the proportions in this case are simply the proportions of the study population itself in each age group (rather than the standard population). Try to reproduce the crude and age-adjusted death rates in Tables 1 and 2 using this weighted sum method! Any minor differences are due to rounding.

An age-adjusted death rate is a summary measure that condenses a lot of information into one figure. Where feasible, it is always desirable to inspect the age-specific death rates of the populations being compared. This additional detail often provides further insights into the nature of the mortality differences between the populations.

Indirect Method

The indirect method of age-adjustment applies the age-specific death rates of the standard population to the age distribution of the study population in order to generate expected deaths in the study population. These are the deaths that would occur in the study population IF the agespecific death rates in the standard population were in operation. This method may be used in situations where the numbers of deaths in each age group in the study population are too small to calculate stable age-specific rates. Also, this method is often used in developing countries or other areas where there is no information available on age-specific deaths for the study population, but there is such information available for a national or standard population. The expected deaths are then summed across the age groups and compared to the actual or observed number of deaths for the study population. This ratio of observed/expected deaths is often referred to as the **standardized mortality ratio**, or SMR. A ratio greater than 1.0 indicates higher mortality in the study population compared to the standard population (controlling for age distribution), while a ratio less than 1.0 indicates lower mortality in the study population. The SMR controls for age distribution since both the observed and expected deaths are based on the age distribution of the study population. Multiplying the SMR times the crude death rate in the standard population produces the **indirectly standardized death rate** for the study population.

Table 3 presents an example. The age-specific death rates in the 1993 North Carolina standard population (column 2), after moving the decimals three places to the left, are multiplied by the 1991-95 Hertford County population in column 1 to produce the expected deaths in column 3. These expected deaths by age may be compared to the actual 1991-95 deaths by age in Hertford county, shown in column 1 of Table 1. Dividing the 1,336 total deaths observed in Hertford County during 1991-95 by the 1,187 total expected deaths results in an SMR of 1.13. This indicates that the 1991-95 death rate in Hertford County was on the whole higher than the rate in the 1993 North Carolina standard population, controlling for age. Multiplying the crude death rate in the standard population of 9.0 by 1.13 gives an indirectly standardized death rate for Hertford County of 10.2. It is usually desirable to use a standard population that is close to the same year(s) as the data for the study population, to avoid differences between the observed and expected deaths due to changing (often declining) age-specific death rates over time. This is why the 1993 (midpoint) North Carolina standard was used in this example.

Table 3
Age-Adjustment by the Indirect Method
Hertford County, North Carolina Residents
1991-1995 Combined; All Causes of Death

	1	2	3
Age Group	Hertford County 1991-95 Population	Age-Specific Death Rates in 1993 North Carolina Standard Population (per 1,000)	Expected Deaths in Hertford County
0-4	8,150	2.44	20
5-14	17,109	0.25	4
15-24	16,601	0.98	16
25-34	14,872	1.53	23
35-44	16,199	2.55	41
45-54	12,381	5.03	62
55-64	10,277	12.41	128
65-74	9,370	28.48	267
75-84	5,631	63.19	356
85+	1,829	147.85	270
Total	112,419	9.0 (Crude Rate in Standard)	1,187
	Standardized Mortality Ratio (SMR)	= 1,336 ÷ 1,187	
		= 1.13	
	Indirectly Standardized		
	Mortality Rate	$= 1.13 \times 9.0$	
		= 10.2	

Comparison of the Direct and Indirect Methods

The direct method of adjustment is generally preferred where the numbers of deaths in the study population are large enough to produce stable age-specific death rates. A big advantage of the direct method is that the adjusted rates of a number of different study populations (e.g. all counties in North Carolina) can be directly compared to each other if they are all adjusted to the same standard population. This allows mortality comparisons assuming a constant age distribution across all of the study populations. The indirect method is often used if mortality rates by age cannot be calculated for the study population, or if the numbers of deaths in the study population are too small to produce stable age-specific death rates. A problem with the indirect method is that the adjusted rate for the study population can be compared only with the rate of the standard population. Different study populations cannot be compared to each other since the adjusted rates are not based on a common age distribution. In other words, differences in the rates may still be due to differences in age distribution, since the rates are adjusted to the age distribution of each particular study population rather than to a common standard.

Issues in the Choice of the Standard Population

An age-adjusted death rate is a hypothetical index, designed to facilitate comparisons among populations, rather than a true measure of risk. An age-adjusted death rate (by the direct method) answers the question: What would the death rate in a study population be IF that population had the same age distribution as the standard population? So in theory any population distribution can be used as the standard; it is only a set of weights applied to the age-specific death rates. The choice of the standard population will not usually have a great effect on the **relative** levels of the age-adjusted rates that are being compared. But it is important to remember that age-adjusted death rates can be compared to each other **only** if they are adjusted to the same standard.

For many years the National Center for Health Statistics has used the 1940 United States population as the standard for age-adjusting death rates. Converted to a population of one million with the same proportions at each age as in the 1940 population, this standard is sometimes referred to as the "standard million." An advantage of consistently using this same standard population is that it promotes comparisons of age-adjusted death rates, especially in looking at trends over time from 1940 to the present. A disadvantage of using this standard is that the size of the adjusted rate is often much different from the size of the crude rate in the study population.

Take the example of heart disease mortality in North Carolina. In 1993 the crude heart disease death rate was 277.0 per 100,000 population. Age-adjusted to the 1940 United States population standard, the 1993 heart disease death rate for North Carolina was 151.4. The 1993 United States heart disease death rate, age-adjusted to the 1940 United States standard, was 145.3. This shows that the 1993 heart disease death rate in North Carolina was slightly higher than that in the United States, after adjustment for differences in age distribution. However, the North Carolina adjusted rate of 151.4 is much lower than the crude rate in 1993 of 277.0 (i.e. it is not an accurate measure of the risk of death from heart disease in 1993). This is primarily due to the following: a) the 1940 United States population is much younger than the 1993 North Carolina population, and b) heart disease death rates are much higher in the older age groups. So standardizing to a much younger population results in a much lower age-adjusted death rate. In recognition of this

problem, the National Center for Health Statistics has proposed to begin using the year 2000 United States population as the recommended standard population. This will mean that the age-adjusted death rates will generally be much more similar in size to contemporary crude death rates. However, it will also mean that time series comparisons of age-adjusted death rates will have to be re-computed using the new standard, and that rates adjusted to the 1940 standard cannot be compared to rates adjusted to the new standard.

For a number of years the State Center for Health Statistics used the current-year North Carolina population as the standard for computing adjusted rates in the annual publication *Leading Causes of Death*. This was not a problem as long as comparisons of adjusted rates were made within the current year. It did, however, preclude comparisons of adjusted rates over time since the standard population was changed every year. To address this problem, beginning in the late 1980s, the State Center for Health Statistics started using the 1980 North Carolina population as the standard for adjustment in each annual publication. This made it possible to compare adjusted death rates for different years. But as the North Carolina population has become older over time, the current-year crude death rates have generally become increasingly different in size from the adjusted death rates. In the 1996 edition of *Leading Causes of Death* we changed from computing age-race-sex-adjusted death rates to computing age-adjusted rates. (The reasons for this are discussed below.) Since the adjusted rates for 1996 forward would not be comparable to previously published rates anyway, we took this as an opportunity to update the standard population to the 1990 North Carolina population by age, which has made the crude and adjusted death rates less different in size than when the 1980 standard population was used.

Taking the example of Hertford County, the 1991-95 crude death rate was 11.9 and the age-adjusted death rate using the 1980 North Carolina population as the standard was 8.7. Using the 1990 North Carolina population as the standard, the 1991-95 age-adjusted death rate for Hertford County for all causes of death is 10.0. The main reason that this latter adjusted rate is higher is because the 1990 North Carolina population used as the standard is older than the 1980 North Carolina population.

One should be especially careful when assessing trends over time using age-adjusted death rates. It is essential that rates for different years be adjusted to the same standard population before making comparisons. Also, if the standard population is very different from the populations of the years being compared (as is often the case when using the 1940 U.S. standard), changes in the adjusted rates over time may not be an accurate reflection of the actual changes in the risk of death.

Errors of Adjusted Rates

A detailed discussion of random errors in age-adjusted death rates is beyond the scope of this paper. The reader should refer to the Statistical Primer cited in reference 1 for information on the general concepts of random errors in rates, confidence intervals, and determining if the difference between two rates is statistically significant. Using the terminology in that paper, a 95% confidence interval around a proportion can be computed as

$$p \pm 1.96 \sqrt{pq/n}$$

The $\sqrt{pq/n}$ is commonly known as the **standard error** of the proportion. In this case a death rate is treated as the proportion (p) who died during the time period of interest. If the proportion who died is small, then q (which is 1-p) will be very close to 1.0 and the formula becomes $\sqrt{p/n}$, where n is the population or the denominator of the proportion.

We saw from the discussion above that an age-adjusted death rate (by the direct method) is a weighted sum of the age-specific death rates. Using ten age groups, the formula for the standard error of an age-adjusted death rate is as follows:

$$\sqrt{\frac{10}{\sum_{i=1}^{\infty} w_i^2(p_i/n_i)}}$$

This is the square root of the sum across the ten age groups of the square of the weight times the standard error of the age-specific death rate squared. Remember that the weight is simply the proportion of the standard population in age group i. This standard error of the age-adjusted death rate times 1.96 is the half-width of the 95% confidence interval around the age-adjusted rate.

This is a very brief discussion of a lengthy topic. For questions or assistance, contact the author.

Issues in Adjusting for Race and Gender

For many years, the death rates in the *Leading Causes of Death* publication of the State Center for Health Statistics were adjusted simultaneously for age, race, and gender. This was done for five-year death rates for specific causes of death, by county of residence. With 40 age-race-gender-specific rates being computed for the adjustment process (10 age groups x 2 race groups: white/minority x 2 gender groups), it became apparent that the data were being spread too thin. A particular problem was in the western North Carolina counties, which generally have very small minority populations, and there were also problems in other counties with a small population. Just one or two deaths in a small population group could result in a very high age-race-gender-specific rate, which would severely inflate the adjusted death rate. If this rate were applied to the appropriate age-race-gender group of the standard population, a very large number of expected deaths could result and the adjusted rate would be extremely high. On the other hand, zero deaths in several population groups may result in a very low age-race-gender-adjusted rate.

For example, in the 1995 Leading Causes of Death publication of the State Center for Health Statistics, Macon County was shown to have a 1991-95 age-race-adjusted death rate for female breast cancer of 64.6 (per 100,000 population) compared to the age-race-adjusted rate for North Carolina of 28.3. (Breast cancer death rates are already gender-specific and do not need to be adjusted for gender; in this case there were 20 age-race-specific death rates.) The 1980 North Carolina population was used as the standard for adjustment. Further investigation showed that this very high adjusted rate of 64.6 was due to two breast cancer deaths in a very small minority female population group (ages 55-64). When the 1991-95 breast cancer death rate was adjusted

only for age, the Macon County rate was 30.4 compared to a North Carolina age-adjusted rate of 25.6. The crude 1991-95 breast cancer death rates for Macon County and North Carolina were 56.5 and 32.1, respectively. Adjusting only for age avoids the bias due to small numbers, and the similar size of the county and state age-adjusted rates appropriately shows that the elevated crude death rate for breast cancer in Macon County was due mainly to an older population distribution in Macon County compared to North Carolina as a whole.

Age generally has a much stronger impact on mortality than race or gender, and therefore is the most important factor to adjust for. Also, there are other questions about adjusting for race. Age differences in mortality are not easily modified. Racial differences in mortality, on the other hand, are often due to factors that can be changed through public health, medical care, or socioeconomic interventions. Adjusting for race may cover up the fact that certain geographic areas, for example, have higher mortality because they have a larger percentage of minority populations (who often have higher death rates). In many cases we would want to target these areas for public health interventions and not produce statistics that adjust downward a higher level of mortality that is potentially modifiable.

For example, it was shown above that the 1991-95 age-adjusted death rate for Hertford County for all causes of death (using the 1980 North Carolina population as the standard) was 8.7 per 1,000, compared to the 1991-95 age-adjusted death rate for North Carolina (using the same standard) of 7.4. If the 1991-95 Hertford County death rate is age-race-gender-adjusted to the 1980 North Carolina population, the resulting adjusted rate is 7.7 and the comparable age-race-gender-adjusted rate for North Carolina is 7.4. This shows that the age-race-gender-specific death rates in Hertford County were similar to those in the state as a whole, but does not reveal that Hertford County had a higher overall mortality rate than the state due to a higher percentage of minorities. Minorities (primarily African Americans) are approximately 61 percent of the total population in Hertford county, compared to 24 percent for the state as a whole.

Rather than adjusting for race, a better approach would be to examine racial differences in mortality by calculating race-specific death rates, perhaps adjusted for age. Minority populations often have a younger age distribution than whites. Adjusting for age usually results in relatively higher death rates for minorities, and larger differences between whites and minorities than when comparing crude death rates. In adjusting the death rates of different race (or race-gender) groups for age, it is important to use the same standard population (or set of age-specific weights) in all cases so that the adjusted rates will be directly comparable. At the county level in North Carolina, small numbers of deaths generally preclude calculating statistically reliable death rates for minority populations other than African Americans. For this reason, we usually calculate death rates for two broad racial groups: white and all minorities combined. In North Carolina as a whole, African Americans comprise more than 90% of the minority population. (Hispanics are considered an ethnic rather than a racial group and most Hispanics are counted within the white racial group). Another problem with calculating death rates for specific minority sub-groups is the lack of accurate population estimates to use in the denominators of the death rates.

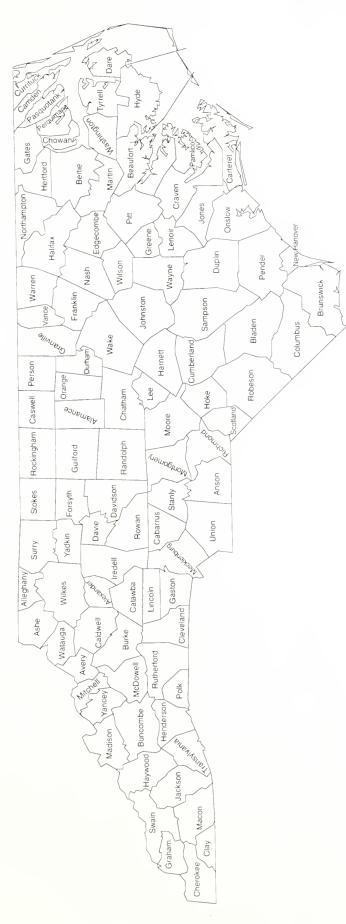

For the reasons discussed above, beginning with the 1996 *Leading Causes of Mortality* publication, we have adjusted all death rates only for age, using the 1990 North Carolina population in ten age groups as the standard.
